The measuring elements assembly, shown partly in section in Figure 2, includes a resistance thermometer bulb, a conductivity cell, and a Bourdon pressure element. The resistance bulb has a thermal time constant of 0.45 second and is capable of withstanding external pressures in excess of 2,000 pounds per square inch. It is constructed by drawing a number of strands of enamelled nickel wire into a long, small-diameter, thin-walled copper capillary tube, sealing the ends, and winding the tube on an open frame to form a helix. The connections are brought out through one end with kovar-glass sealed terminals. The conductivity cell is made up of a plastic tube sheathed in heavy bronze tubing and includes three coaxial platinum-lined electrodes, one in the center and one at each end. The Bourdon depth element is made of a beryllium copper alloy. Its free end carries a contact which moves across a slide-wire, converting a position measurement to an electrical value which can be easily transmitted. A single 9-conductor waterproof cable connects the measuring elements assembly to the recorder. The several sections comprising the housings for the measuring elements are bolted together, using confined rubber gaskets to make the complete unit pressure tight.

The computing and recording mechanisms are mounted on a steel frame enclosed in a wood case having removable sides and top cover. The top view of this

unit is shown in Figure 3. The measuring and computing mechanisms are electromechanical servo systems. The chart drive mechanism is provided with a speed change lever which can be used to change the chart feed rate from a given number of inches per hour to the same number of inches per minute. In addition, several sets of change gears are provided to permit many different chart speeds to be obtained. The maximum speed is 12 inches per minute. The three recording pens deflect about a common axis, and each uses a characteristic color of ink for making its record. A fourth pen, fixed in position, indicates any lateral departure of the chart, making it possible to correct the readings should a departure occur. The chart has 62 uniform divisions and has printed on it three sets of scales, one for each of the required measurements. One division on the chart corresponds to the following increments; 1 degree Fahrenheit in temperature, 0.2‰ in salinity, and 20, or 10, feet in depth, depending upon the calibration of the depth measuring element. Two salinity ranges are provided; 20 to 32‰ and 28 to 40‰, a switch being used for setting the desired range. The specific conductance of the sea water is indicated by a dial visible through a window in the front of the case.

Four identical amplifiers, housed in a single open-type case, are used to increase the power available from the measuring and computing circuits to a level sufficient for operating the various balancing motors. All of the electrical connections to each amplifier are made with a single plug-type multiple connector.

The mechanical construction of the instrument is sturdy, and it will not be damaged by reasonably rough handling. Where fixed mechanical relationships must be maintained for accurate performance, the units involved are pinned together or to supporting structural members with close-fitting dowels. All metal parts are protected from corrosion by Navy-approved methods for shipboard equipments.

In order to prevent ambient temperature errors all fixed resistors and slidewires in the measuring and computing circuits are wound with resistance wire having a negligible temperature coefficient. To insure long satisfactory performance, all capacitors and transformers used in the instrument are sealed hermetically.

Discussion of Design

Temperature System

The selection of a resistance thermometer for the temperature measuring element was made after considerations were given to various types of systems. These included the resistance thermometer, liquid-filled and vapor-tension type bulbs, and thermocouples. The systems were compared for accuracy, reproducibility, speed of response, scale distribution, and measuring and servo system requirements. The resistance thermometer arrangement was selected because it appeared to offer the best compromise among these factors.

Resistance thermometer bulbs can be reproduced with an accuracy of 0.1 degree Fahrenheit or better, and by suitable design the time constant can be made small, in the order of one-half second. The scale distribution, which depends upon the type of temperature-sensitive wire and the circuit used, can be made nearly linear. A simple Wheatstone bridge circuit energized from an a-c source can be used to measure the resistance of the thermometer bulb.

Figure 1. Shipboard installation of salinity-temperature-depth recorder

Variations in the supply voltage affect only the sensitivity of measurement. A simple a-c electronic amplifier can be employed to provide the necessary output power, and the performance of the system can be made so that large variations in the contact resistance are negligible.

Conductivity System

Laboratory measurements of the electrical conductivity of a solution are usually made with a 2-electrode cell and a Wheatstone bridge circuit. When this type of cell is immersed in a solution the measured conductance includes the conductances of the paths within and external to the cell. Since the cross-sectional area of the external shunt path may be very large for a cell submerged in the sea, its conductance will be large compared to the conductance within the cell. A cell with an electrode at each end may be effectively short-circuited when used in this way.

To avoid this difficulty a cylindrical cell with three coaxial electrodes is used. One electrode is in the center of the cell and one at each end. The two outer electrodes are connected together electrically, and the potential is applied between them and the center electrode. The lead to the center electrode is insulated, and approximately half of the current in this lead flows through the sea water sample to each end electrode. The two paths from the center electrode being in parallel, the measured conductance is the sum of the conductances of these paths. As the two outer electrodes are short-circuited together, they are at the same potential and no current will flow between them through any external shunt path. Thus, the measurements are independent of external shunt conductances and the cell constant may be determined without the need for duplicating the actual conditions of use. Moreover, this permits the use of a heavy protective metal sheath around the cylindrical cell, eliminating the possibility of shock damage to the plastic tubes which comprise the cell body.

A Wheatstone bridge circuit can be used to measure the conductance of the sea water in the cell, the bridge being energized from an a-c source.

Depth System

The depth of a measuring element can be determined best by measuring the sea pressure at that depth. Pressure is related to depth by considering the average specific gravity of the sea water to be 1.025. Although the actual specific gravity may differ from this value because of temperature and salinity conditions, the integrated error is usually negligible.

Pressure is most simply measured with calibrated spring elements, such as Bourdon tubes or bellows arrangements. The choice between these is governed by the factors; required power output, permanence of calibration, freedom from hys-

Figure 2. Section view, measuring elements assembly

teresis, mechanical simplicity, and physical size. Experience with both of these types indicated that, for the pressure range involved, the Bourdon helical element offered the best compromise among these factors. This type, when used to move a contact across a slide-wire, permits the use of a simple bridge circuit for measuring the pressure, together with an amplifier and servo system identical to those used for the other measurements.

Salinity Computing Circuit

A circuit arrangement for obtaining salinity directly from simultaneous measurements of temperature and conductivity was preferred to the use of a temperature compensating cell as employed in previous instruments.[4,6,8,9] The slow response of a sealed cell designed to withstand the necessary pressure makes it less useful in a hydrographic instrument.

The use of a sealed reference cell in a bridge circuit for determining salinity does not provide exact compensation even when the sample water and the water in the sealed cell are maintained at the same temperature. An examination of the errors shows them to be only slightly less than those for the computing arrangement employed in the present instrument. However, serious errors may result from the difference in temperatures of the water in the measuring and reference cells caused by the thermal lag of the reference cell. Since it was expected that a resistance thermometer bulb could be made with less thermal lag than a sealed cell designed for the same pressure, thus permitting the high-speed performance desired, the computing method was selected.

Figure 3. Recorder, top view

The mathematical functions employed for the computation of salinity were derived from published data[10] relating conductivity to chlorinity and temperature. These data were translated to provide salinity as a function of conductivity and temperature by the use of the relationship

$$\text{Salinity} = 1.805 \times \text{Chlorinity} \qquad (1)$$

in which chlorinity is defined as the total amount of chlorine, bromine, and iodine in grams contained in one kilogram of sea water, assuming that the bromine and iodine had been replaced by chlorine. This expression differs by $0.03^0/_{00}$ from the empirical equation

$$\text{Salinity} = 0.03 + 1.805 \times \text{Chlorinity} \qquad (2)$$

which was established by an International Commission[11] based on samples collected from the Baltic Sea. Since the maximum possible error arising from the use of equation 1 instead of equation 2 amounts to only $0.03^0/_{00}$ and is less than the expected error of the instrument, the employment of the simpler relation is justified. Figure 4 shows the relationships between the specific conductance of sea water and the salinity for the temperature range 30 to 90 degrees Fahrenheit.

When these data are plotted with temperature as the parameter, all of the curves of the family obtained diverge from the origin, and each is slightly concave toward the salinity axis. When the logarithms of salinity are plotted against the logarithms of conductivity for each temperature value, all of the curves are approximately parallel and very nearly straight lines. If they were exactly straight and parallel, it would be possible to represent salinity precisely by the product of two independent functions; one of temperature, and the other of conductivity. By adjusting these curves so that this condition exists, an approximate function of this form is obtained. This complete family of adjusted curves can be represented with reasonable accuracy by the empirical equation

$$S = \left(\frac{100{,}000}{25.661 + 0.73720T} - 348.87\right) c^{1.0946} \qquad (3)$$

where S is the salinity in parts per thousand, T the temperature in degrees Fahrenheit, and c is the specific conductance in mhos per centimeter cube. This particular approximation was selected to give the error distribution indicated in Figure 5. It will be noted that the least errors are incurred for salinities between 30 and $35^0/_{00}$. The average salinity of the surface waters of the oceans is about $35^0/_{00}$. In

Figure 4. Salinity of sea water from temperature and specific conductance

Figure 5. Theoretical salinity error curves

coastal waters it is approximately 32‰. Only in some of the enclosed seas in geographical areas where the evaporation exceeds the precipitation, such as the Mediterranean and Red Seas, does the salinity approach 40‰. Salinities less than 30‰ are encountered in coastal areas near river mouths and in some enclosed seas, as the Black Sea and the Baltic.

In order to perform the computation indicated by equation 3, mechanisms are required for deriving the necessary functions from independent measurements of temperature and conductivity, for multiplying these functions, and for indicating the product by the position of a pen on a chart. Although a much simpler mechanism can be employed for obtaining salinity when a sealed reference cell is used, the computing system was selected as the most practical arrangement chiefly because it makes rapid continuous measurements possible by reducing the time lag to that of the thermometer bulb.

Discussion of Circuits

Amplifiers and Servomotors

In order to provide the power necessary to operate the computing and recording mechanisms the output of each bridge circuit must be amplified. All of the measuring and computing circuits are energized with alternating current of line frequency. The output from each bridge is supplied to an independent electronic amplifier which operates the balancing servomotor of the bridge.

Each amplifier includes a rectifier tube, three stages of resistance-coupled voltage amplification, and a power stage. The tubes are operated below normal ratings to increase their useful life, and ordinary variations in their characteristics have no effect on the performance of the systems. The input resistance of each amplifier is approximately one-quarter megohm, and as the measuring and computing circuits are used in a null-balance manner, large changes in the resistances of the sliding contacts have only small effects on the sensitivities of the measurements. By incorporating a gain control in each amplifier the same type of amplifier serves for both the measuring and computing circuits.

The servomotor employed with each circuit is a small 2-phase induction motor, one phase being energized from the line and the other from the amplifier output. Its direction of rotation depends upon the relative phase of the amplifier output voltage with respect to the line and its speed is a function of the magnitude of this voltage. The slide-wire contacts and their associated recording pens are geared to their respective motor shafts, so that a direct relationship exists between them. The time for full-scale deflection of each of the measured and recorded quantities is approximately five seconds.

Temperature Circuit

Figure 6 is a diagram of the Wheatstone bridge circuit used for the temperature measurement, in which *R6* represents the thermometer bulb, connected to the circuit by three leads, *R1* is a slide-wire, and *R2*, *R3*, *R4* and *R5*, are fixed resistances. Voltage is applied to the bridge from step-down transformer *T1*, and the bridge output is connected to an amplifier. When the bulb temperature changes, the resulting bridge unbalance is amplified to operate a servomotor and move the slide-wire contact to a new position of equilibrium. The position of the contact then represents the temperature at the thermometer bulb.

The calibration equation of the Wheatstone bridge circuit can be derived by setting to zero the expression for its output voltage. Designating e_1 as the voltage applied to the bridge from the transformer *T1*, *P* the resistance of *R1* and *R2* in parallel, *L1* the resistance of each lead wire, and x the resistance of the fraction of *P* between the bottom end of the slide-wire and its contact, then for balance

$$\left(\frac{e_1-i_1L_1}{L_1+P+R_3+R_4}\right)(L_1+R_3+x)-\left(\frac{e_1-i_1L_1}{R_5+R_6+L_1}\right)(R_6+L_1)=0 \quad (4)$$

where i_1 is the current in the transformer branch. Defining

$$R_6=R_{28}+r_1 \quad (5)$$

where R_{28} is the resistance of the thermometer bulb at 28 degrees Fahrenheit and r_1 is the change in the resistance from 28 degrees Fahrenheit to the temperature measured, and by constructing the resistances so that

$$R_3=R_{28} \quad (6)$$

$$\text{and } P+R_4=R_5 \quad (7)$$

equation 4 can be rearranged to give

$$x=\frac{R_5r_1}{R_{28}+r_1+L_1+R_5} \quad (8)$$

As e_1 and i_1 do not appear in this equation the calibration is independent of the applied voltage.

The magnitude of the fractional error

caused by a change of lead resistance can be determined from the derived equation

$$\frac{dx}{x} = -\frac{dL_1}{R_{01}+r_1+L_1+R_5} \tag{9}$$

By making the denominator large compared to the expected dL_1, it is possible to keep small the effects of changes in lead length on the calibration. For the circuit values used a change in lead resistance of 2.5 ohms will cause an error of only 0.1 degree Fahrenheit at full scale, and one-half this error at mid scale. This resistance corresponds to approximately 400 feet of number 18 copper wire. By calibrating the 3-lead circuit for a nominal value of lead resistance, large changes in the lead length can be tolerated.

An expression for the resistance of the thermometer bulb at temperature T is

$$R_8 = R_{01}(1+a(T-28)+b(T-28)^2) \tag{10}$$

where a and b are constants for the wire material. If

$$t = T-28 \tag{11}$$

from equations 5 and 10

$$r_1 = R_{01}(at+bt^2) \tag{12}$$

Substituting 12 in 8

$$x = \frac{R_5 R_{01}(at+bt^2)}{R_{01}(1+at+bt^2)+L_1+R_5} \tag{13}$$

The slope of x with respect to t is

$$\frac{dx}{dt} = \frac{R_5 R_{01}(R_{01}+L_1+R_5)\ (a+2bt)}{[R_{01}(1+at+bt^2)+L_1+R_5]^2} \tag{14}$$

In this equation both the numerator and denominator increase with t, and it is possible by proper selection of R_{01} and R_5 to make the slope practically constant over the full-scale range. The thermometer bulb wire in this instrument is nickel to high purity, and the bridge circuit is designed for this bulb so that the maximum departure of the calibration from a linear scale is only 0.06 degree Fahrenheit.

The measuring sensitivity of the circuit depends on the temperature coefficient of the bulb wire and the current through it. The current used, about 20 milliamperes, is sufficiently low for the bulb construction so that the temperature rise caused by the power dissipated in the winding is negligible. The bulb has a time constant of 0.45 second and consequently gives a response of 90 per cent of the change in one second.

Conductivity Circuit

The conductivity measuring circuit, shown in Figure 7, is a Wheatstone bridge. *R16* is the resistance of the sea water in the cell, *L2* is the resistance of each lead, and *R13*, *R14*, and *R15* are fixed resistances. Transformer *T2* supplies a voltage e_2 to the bridge circuit. The amplifier and servomotor are identical to those used with the temperature measuring system. Designating Q as the resistance of *R11* and *R13* in parallel, and y as the resistance of the fraction of Q between the upper end of the slide-wire and its contact, then, by a treatment similar to that applied to the temperature circuit, it can be shown that

$$y = \left(\frac{Q+R_{14}+L_2}{1+\frac{(R_{14}+L_2)c}{k}}\right)\frac{R_{15}}{k}c \tag{15}$$

where c is the specific conductance of the sea water and k is the cell constant, which are related to *R16* by

$$k = c \times R_{16} \tag{16}$$

The circuit values are selected so that y is equal to Q when c is the full-scale value of specific conductance, c_m.

Since the denominator in equation 15 is not constant, the scale distribution is nonlinear. However, as specific conductance is not directly recorded on the linear chart, but used only for computing salinity, linearity is not necessary. The circuit values used in this instrument cause a maximum nonlinearity of less than two per cent.

As in the temperature measuring circuit, the primary element is connected to its bridge by three leads. Here also the purpose of the 3-lead connection is to keep the errors caused by a change in lead resistance to a small value. If only two leads were used, the sum of their resistances would add directly to the resistance of the sea water in the cell. For the circuit values used in the instrument, a length change of 16 feet of two number 18 wires would introduce an error of 0.1 per cent at full scale.

The bridge resistances are constructed so that

$$Q = R_{13} \tag{17}$$

and

$$R_{14} = \frac{k}{c_m} \tag{18}$$

For these relationships it can be shown that the use of three leads instead of two for connecting the cell to the bridge circuit reduces the maximum error caused by a change in lead resistance in the approximate ratio of eight to one. With the circuit values used in the instrument, a change in lead length of about 125 feet will introduce a 0.1 per cent error.

The constant for a conductivity cell depends on its mechanical dimensions and the sizes, shapes, and surface conditions of the electrodes. Cells of similar design can be readily made having constants within two or three per cent of each other. When a cell is replaced by another having a different constant, the value of the resistance *R15* can be changed to retain the

Figure 6. Temperature measuring circuit

Figure 7. Conductivity measuring circuit

Figure 8. Depth measuring circuit

original calibration for one particular value of specific conductance. For other specific conductances the calibration is altered slightly, the extent of the change depending upon the magnitude of the term $(R_{18}+L_4)/k$ in equation 15. With the circuit components used in the instrument a five per cent change in the value of the cell constant will cause only a 0.08 per cent variation in the calibration curve. Each cell has a separate *R15* resistance spool made for it, and when cells are changed the *R15* spools are also changed.

Another factor affecting the value of the constant of a cell is the phenomenon of polarization, which introduces uncertain errors in the measured conductance. When direct current is passed through a solution, the products of electrolysis accumulate at the electrodes and no constant value of conductance can be determined. With alternating current the ions are not discharged at the electrodes. However, there are still some polarization effects, which are attributed to variations in the ionic concentrations near the electrodes. To obtain good accuracy the effects of polarization must be kept small. This can be accomplished by using a cell with electrodes of large surface area and a large constant and by employing high a-c frequencies. A common method for increasing the effective area of an electrode is the application of a coating of platinum black to its surface. Tests made by Kohlrausch and Holburn[12] indicate that polarization is negligible for platinized electrodes when the area of the electrode in square centimeters is greater than $50\times C$, whereas 0.1 per cent accuracy can be obtained with bright electrodes whose area is greater than $2{,}500\times C$, C being the measured conductance expressed in mhos. Experiments by Thuras[4] have shown that the difference in polarization between 1,000 and 60 cycles is quite small, being in the order of 5 parts in 100,000. Because of its availability, and as it permits the use of the same type amplifier employed with the temperature circuit, 60-cycle alternating current is used for the conductivity circuit.

Another effect of polarization is to produce an apparent high capacitance in series with the conductance of the cell. The reactance of this capacitance is in quadrature with the conductance, and it does not change the measured conductance in proportion to its magnitude. However, it does affect the sensitivity of detecting the balance condition of the circuit and it becomes more important at the lower frequencies. Platinization of the electrodes increases the value of the series capacitance, making its reactance smaller. During the experimental stages of the development of this instrument it was observed that for the cell and electrode arrangement used, the ratios of the series capacitances to the conductances were approximately constant for all salinities within the working range. This ratio is the cotangent of the phase angle between the applied voltage and the resulting current. If the phase angle were exactly constant for a cell it would be possible to cancel completely the quadrature component of the circuit output by introducing the capacitor *C3* across the resistance *R14* to shift the phase of the current in the balancing branch of the circuit an equal amount. This capacitance is determined from the relation

$$C_3=\frac{\tan N}{2\pi f R_{14}} \tag{19}$$

where N is the phase angle of the cell and f is the frequency. By applying a capacitor in this manner the need for platinum-black coatings on the electrodes was avoided.

Depth Measuring Circuit

The depth measuring circuit, shown in Figure 8, is a double slide-wire bridge. *R36* is the slide-wire in the transmitting unit, the contact of which is positioned by the free end of a helical pressure spring. *R37*, *R38*, and *R39* are fixed resistances in the transmitter. *R31* is the slide-wire in the recorder, whose contact is actuated by a servomotor and mechanically connected to the depth recording pen. *R32*, *R33*, *R34*, and *R35* are fixed resistances in the recorder. The resistance of each lead is indicated by *L3*. Transformer *T3* applies a voltage e_3 to the bridge, and the amplifier unit amplifies any unbalance and causes the servomotor to move the recorder contact to restore a condition of balance. In a conventional bridge of this type the amplifier is normally connected between the two sliding contacts, rather than as shown in Figure 8. With a high-input impedance amplifier this arrangement has the advantages of providing uniform sensitivity over the scale range and being unaffected by large changes in the

Figure 9. Salinity computing circuit

Figure 10. Surface recording in vicinity of sewer outfall at New Bedford, Mass.

Figure 11. Surface recording in Mount Hope Bay

contact resistances. However, as the lead to the transmitter contact is in the long cable connecting the measuring elements assembly to the recorder, it is subject to inductive effects from the currents and voltages of the adjacent leads connecting to other circuit elements. These can directly introduce errors in the depth measurements, depending upon the amplitude and relative phase of the resultant pickup. To avoid this possibility of error, the voltage supply is connected between the two sliding contacts. Here, the same degree of pickup in the cable lead has a negligible effect because of the relatively large measuring current flowing in it. This is consistent with the connections of the temperature and conductivity circuits, where the amplifier input leads which are sensitive to pickup are all in the on-board equipments, and can be kept short and be properly shielded. This arrangement has the disadvantage of causing variable measuring sensitivity over the depth scale and less protection against variations in the contact resistances. However, by making the resistance of *R35* high, and the effective resistances of the slide-wires low, in relation to the resistances on each side of the slide-wires, these disadvantages become negligible. By doing this there is considerable attenuation of the useful power, but as the total power supplied to the bridge is small this is not a serious matter.

Designating the parallel resistance of *R31* and *R32* by *M*, the parallel resistance of *R36* and *R37* by *N*, with *v* and *u* representing the fractions of *M* and *N* respectively, from the left-hand end of each slide-wire to its contact, and by constructing the resistances so that

$$M = N \tag{20}$$

and

$$R_{33} = R_{34} = R_{38} = R_{39} \tag{21}$$

then the contact position at balance is given by

$$v = \frac{(2R_{33} + M)u + ML_5}{2(R_{33} + L_5) + M} \tag{22}$$

For this circuit arrangement, the maximum error caused by a change in lead resistance can be shown to be represented by

$$\frac{dv}{M} = \frac{dL_5}{2R_{33} + M} \tag{23}$$

Thus, by making the denominator large, the effects of changes in the lead resistance will be small. In the instrument this value is 10,000 ohms, so that a 1-ohm change in lead resistance (160 feet of number 18 wire) will cause a maximum error of only 0.01 per cent.

The depth elements for the different ranges are made interchangeable by setting the fixed resistances associated with each element in accordance with the relations indicated in equations 20 and 21.

Salinity Computing Circuit

Figure 9 is a diagram of the circuit used for computing salinity from the simultaneous measurements of conductivity and temperature. Slide-wire *R21* is connected across the line, and its movable contact is positioned from the shaft of the conductivity unit according to a specific function of conductivity. The current in the temperature compensating slide-wire *R41*, connected to the secondary of transformer *T4*, is proportional to this same function, and its contact is positioned by the shaft of the temperature unit. The output voltage of *R41* is, therefore, proportional to the product of the conductivity and temperature functions. The current in slide-wire *R61* is supplied by transformer *T5*, the primary of which is connected to the power line. The transformers are used only to isolate the computing circuits from the line, each transformer having unity voltage ratio. When the voltage is zero between the contacts on slide-wires *R41* and *R61* the position of the contact on *R61* represents the product of the conductivity and temperature functions given in equation 3, which is the salinity. Any change in this product causes an output voltage, which is amplified, and operates the servomotor to move the *R61* contact to a new position of equilibrium. *R42* through *R55* and *R62* through *R67* are fixed resistances. The switch associated with slide-wire *R61* serves to set the range of the salinity circuit. For the switch position shown the range is 20 to

LAT.: 39°16.6 N – LONG.: 69°52.7 W
SALINITY SCALE 28–40‰

Figure 12. Surface traverse across edge of Gulf Stream

32‰. The amplifier and servomotor are identical to those used with the other measuring systems.

Designating the resistance of *R41* paralleled by the series resistances *R43* through *R54* by *H*, and the parallel resistance of *R61* and *R62* by *J*, with *w*, *z*, and *s* representing the effective variable resistances, as shown in Figure 10, then it can be shown that the amplifier input is zero when the three contact positions, *w*, *z*, and *s*, are related so that

$$s = \left(R_{42} + R_{43} + J + \frac{R_{44}R_{45}}{R_{43} + R_{44}}\right) \times \left(\frac{w}{R_{21}(R_{42} + H + R_{55}) + w(R_{21} - w)}\right)(R_{55} + z) - \frac{R_{55}R_{54}}{R_{55} + R_{54}} \tag{24}$$

As voltage does not appear in equation 24 the balance position is unaffected by variations in the supply. This equation for *s* can be expressed in simplified form by

$$s = Af_1(w)f_2(z) - B_1 \tag{25}$$

Where *f* indicates the functions of the respective variables and *A* and *B1* are constants. The function of *w* includes the loading effect of the temperature-compensating circuit on slide-wire *R21*, but does not consider the added load of the exciting current of transformer *T4*. This load, which is kept low by using a transformer with a large number of turns, is taken into account in the initial calibration of the instrument.

The contact of slide-wire *R21* is positioned according to the required function of specific conductance and modified for the loading effects by means of a cam asso-

ciated with the output shaft of the conductivity unit. The contact on slide-wire *R41* is moved directly by the output shaft of the temperature unit, and its position is linearly related to temperature. The required function of temperature is obtained by using the proper distribution of effective resistance in the slide-wire. This is accomplished by tapping the linear slide-wire winding at several points and shunting each section separately with a fixed resistance. This method approximates the continuous curve by a series of straight-line sections, the approximation becoming better as more sections are employed. In the instrument 12 sections are used in slide-wire *R41*, which together with the associated shunting resistances, *R43* through *R54*, provide an approximation with a maximum error of 0.05 per cent.

Large changes in the resistances of the contacts on slide-wires *R41* and *R61* are negligible, as they are in series with the high resistance input of the amplifier. A change in the resistance of the contact on slide-wire *R21*, however, will affect the accuracy of the computation because it alters the voltage applied to transformer *T4*. The error resulting from this condition can be minimized by making the equivalent impedance of the transformer and its load large compared to the resistance of *R21*. No difficulty has been encountered in practice with this arrangement.

The first step in the design of the computing circuit is the selection of a conversion factor relating salinity units to resistance or voltage units. Although this selection is made arbitrarily, the choice of the factor is restricted by consideration of circuit output sensitivity, applied voltage, and the physical properties of the slide-wires. The factor used in the instrument is 80 ohms per part per thousand of salinity.

The salinity range of the chart is determined by the position of the double-pole double-throw switch. Thus, for the position shown, the *B1* constant in equation 25 is equivalent to $20^0/_{00}$. When the switch is in the high-range position

$$B_1 = R_{62} \tag{26}$$

which is equivalent to $28^0/_{00}$. The *A* constant is then

$$A = R_{67} + \frac{R_{62}R_{63}}{R_{62}+R_{63}} + J + R_{64} \tag{27}$$

The resistances are proportioned so that

$$R_{62} + \frac{R_{62}R_{64}}{R_{62}+R_{64}} = \frac{R_{63}R_{65}}{R_{63}+R_{65}} + R_{64} \tag{28}$$

Thus, the constant *A* has the same value for both switch positions, maintaining the same current through slide-wire *R61* for each of the salinity ranges.

The parallel arrangement of resistances is used so that the switch contacts will be in series with the high resistance shunts, thus making negligible the effects of varying switch contact resistances.

Use at Sea

Several of the salinity-temperature-depth recorders have been made and are being used regularly at sea. An earlier model, which recorded salinity and temperature only, has been in use for nearly three years. These instruments have proved to be well adapted to securing continuous measurements from a moving vessel. For determining surface water conditions, the measuring elements assembly may be mounted on the hull below the water line, where the conductivity cell is irrigated by the boat's motion, or inboard in which case it is irrigated by a stream of water maintained with a pump. When used on a small boat, where the intake is within a few feet of the surface, air bubbles are frequently drawn into the circulation and cause undesirable fluctuations in the salinity record. This difficulty did not appear when the measuring elements assembly was installed on an intake line of the research vessel Atlantis which was located 12 feet below the water line. On small boats it may be overcome by mounting the intake tube on a strut which holds it about one foot away from the hull at a depth of two or three feet.

Figures 10 and 11 are illustrations which show how strikingly the instrument records sudden changes in the temperature and salinity of the surface water. In Figure 10 a record is shown taken from a boat which passed directly over the outfall of the sewer at New Bedford, Mass., in the direction in which the tide was flowing. Note the sharp discontinuity encountered upstream of the outfall, the great drop in salinity as the plume was crossed and the gradual increase in salinity which occurred over a distance of 700 yards downstream. Figure 11 shows a sharp discontinuity in salinity encountered in Mount Hope Bay where a tongue of more saline water had become surrounded by dilute water flowing from the Taunton River. The boat entered the saline water at *A*, crossed into more dilute water at *B*, turned and re-entered the tongue at *C* and emerged from it at *D*.

Figure 12 shows a record of the temperature and salinity at a depth of three and one half feet made in a 10-mile traverse across the inshore margin of the Gulf Stream.

Figures 13 and 14 show records of vertical measurements through temperature and salinity gradients. The depth transmitting element used for these surveys was calibrated to give full-scale deflection

of the depth recording pen for 300 feet. The true depths are obtained from the records by dividing by two the readings on the 0–600 scale. These records indicate clearly the usefulness of the instrument for obtaining the hydrography of complicated water structures. It can be noted from Figure 13 that the temperature and salinity are reasonably constant from the surface to a depth of 50 feet, indicating a well-mixed layer. From 50 to 200 feet both the temperature and salinity undergo large changes, but the gradients are not uniform. Below 200 feet both quantities are reasonably constant. The considerable wiggle in the depth trace was caused by the rolling of the vessel. Note how the magnitude of the wiggle is reduced with increasing depth, as the sag in the lengthening cable absorbs the vertical motion of the boat.

Figure 14 shows the very sharp salinity gradient in the estuary of the Thames River at New London, Conn. A shallow layer of fresh water from the river overlays the more saline water from the Long Island Sound. From both the large positive salinity gradient and the negative temperature gradient it is evident that a large positive density gradient exists, indicating a very stable water column with little tendency for vertical mixing.

Experience has indicated the need for taking certain precautions in using the instrument. It was anticipated that serious errors in the measurements of conductivity might result from fouling of the cell with bacterial slime of macro-organisms. A cell has been operated under the wharf at Woods Hole for weeks at a time. Under these conditions the cell constant slowly changes, causing a salinity error of as much as 0.5‰. Under active use during surveys difficulties due to fouling have not arisen, but it is clear that the measuring elements should not be mounted permanently where they are inaccessible to cleaning or are subject to fouling over prolonged periods. Some difficulties caused by inadequate flushing of the conductivity cell have been encountered in vertical surveys, making it necessary to exercise care in controlling the rate of descent of the measuring elements. Further study is being given the cell design with the object of improving its flow characteristic. Improved accuracy over limited ranges of the measured quantities can be obtained by taking calibration samples of water within the ranges and applying fixed corrections to the records.

Conclusions

A practical salinity and temperature recording instrument is described. This type of instrument has been operated regularly for more than three years and has been found useful for obtaining hydrographic data. It has been applied particularly for inshore surveys in shoal water and in ocean areas where its accuracy of 0.2 degree Fahrenheit and 0.3‰ is adequate. Its time constant of one-half second permits continuous records of temperature and salinity to be made from a moving vessel, or while the measuring elements are being lowered vertically.

No Discussion

A New Line of Thyratrons

A. W. COOLIDGE, Jr.
ASSOCIATE AIEE

FOR several years one important application for thyratrons has been their use in controlling d-c motors operated from a-c lines.[1-3] A thyratron acts as a switch, having rectifying properties, and is capable of applying all or any fractional part of the positive half of the a-c cycle to its load. In this way the average voltage applied to a d-c motor may be varied. Precise motor control is obtained by varying the operating angle of thyratrons in either the field or armature circuits or in both circuits simultaneously. Both gas-filled and mercury-vapor thyratrons have been employed successfully with certain limitations for the two types as described in the following:

GAS-FILLED

1. In general, tubes have had low-anode voltage ratings in the order of 500 to 1,000 volts.

2. Tubes have suffered from gas clean-up (or reduction of the gas pressure) causing the control characteristic to shift beyond specified limits, or the tube drop to become excessive, either of which renders the tube inoperable.

MERCURY-VAPOR

1. Restricted ambient temperature range has required either forced draft cooling in compact panels or conversely larger panels in which there is only natural draft available.

2. A cathode preheat period is very often necessary to raise the mercury temperature to within the operating temperature range before anode voltage may be applied.

Paper 48-171, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted December 11, 1947; made available for printing March 12, 1948.

A. W. COOLIDGE, JR., is with the electronic tube department of the General Electric Company, Schenectady, N. Y.

The author acknowledges the assistance of R. E. Wilkes, control division, General Electric Company, who obtained the test data given in this paper.

To meet requirements of the applications, designers of electronic motor-control systems have undertaken to reduce costs and size of the equipment by eliminating many features heretofore deemed necessary to overcome the limitations for mercury and gas-filled tubes.

Tube Specifications

Such a streamlining program called for the development of gas-filled thyratrons having the following characteristics:

1. Maximum cathode heating time of one minute.
2. Small size.
3. Ambient temperature range of minus fifty-five to plus seventy degrees centigrade.
4. Peak to average current ratio of 12:1.
5. Peak forward and inverse anode voltage rating of 1,500 volts.
6. Resistance to vibration and shock.
7. Low cathode power.

The first tube to be developed was the *GL-5545*. This tube has a cathode power of 50 watts and average and peak anode currents of 6.4 and 80 amperes respectively. The over-all size is $2^5/_8$ inches in diameter by 8 inches in length.

Design Theory

Short heating time dictated a filamentary type cathode with little heat shielding, while the high peak current demanded a tenacious cathode coating with the ability to withstand severe ion bombardment. Conventional barium oxide coatings such as are used in receiving tubes and most thyratrons are generally limited in emission to the equivalent of one ampere maximum per square centimeter of emitting surface. Current densities in excess of this value tend to destroy the coating because of excessive ion bombardment. A superior coating which will withstand current densities of three amperes per square centimeter of emitting area may be realized by adding nickel sesquioxide (Ni_2O_3) in a finely divided form to the ingredients of barium oxide coatings. The Ni_2O_3 acts as an agent in fusing the barium oxide to the base metal producing a strong metallic coating as contrasted with the comparatively fragile and powdery conventional coating.

The high conductivity of the resultant metallic coating causes the emission to be well distributed over the surface of the filament and reduces local heating as current travels from the base metal to the surface of the coating.

The attack on the problem of gas clean-up can best be understood by first considering its cause in a thyratron.

During tube conduction, ions positive in potential with respect to the cathode are continuously attracted to the cathode. Some ions gain sufficient velocity to become imbedded in the cathode coating, thereby reducing the total number of free gas molecules and hence reducing the gas pressure in the tube. Normally the tube drop is quite small, however, so that gas clean-up from this action alone is not serious.

By far the greatest clean-up occurs when the anode voltage assumes a high negative value in the presence of ions immediately after conduction. Ions at this time impinge on the anode with sufficiently high velocities to penetrate the surface of the metal and become permanently trapped, and the process continues until the metal directly below the surface becomes saturated. If ion bombardment is particularly severe, material may be sputtered from the anode surface, the resultant sputtered film containing entrapped gas.[4] Thus, during sputtering, a new anode surface is continually made available for further gas absorption. If the gas pressure drops below a value of a few microns, tube failure occurs.

The actual rate and amount of gas clean-up may be a function of both the degree of ionization in the tube at the time of current cessation and the rate at which the inverse anode voltage is ap-

Figure 1. Size contrast between gas-filled GL-5545 and mercury-filled FG-105

Both tubes have an average current rating of 6.4 amperes

plied. Since ions have inertia, the number of ions in a tube at a particular time will be a function of the current through the tube a few microseconds previously. Therefore, the degree of ionization at the time of current cessation is a function of the rate of decay of anode current just prior to this time. Again, because of ion inertia, a finite time is required to deionize the tube, hence the rate of rise of inverse anode voltage determines the severity with which residual ions impinge on the anode. Therefore, when considering the effect that a circuit may have on a gas-filled thyratron, it is convenient to use, as a measure of severity, the product of the rate of current decay in amperes per microsecond prior to commutation, and the rate of rise of inverse voltage in volts per microsecond just after commutation.

If two thyratrons are used in a biphase half-wave rectifier circuit with an inductive load as illustrated in Figure 2, conditions favorable for gas clean-up are realized when the thyratrons are phased to provide continuous load current. The solid line *ABCDEG* represents the voltage across one tube. The counter electromotive force of the inductance maintains a positive anode voltage and forces the tube to conduct long after the supply voltage has gone negative, until at the time of extinction, the voltage changes abruptly to a high negative value. The voltage across the other tube is identical but shifted 180 degrees in phase. The fact that load current is continuous means that both tubes alternately conduct essentially square blocks of current, and that the rate of current decay for the trailing tube during commutation is very high, limited only by the leakage reactance of the transformer.

Considerable field experience with available gas-filled thyratrons of conventional design has clearly demonstrated the fact that circuits which apply inverse voltage abruptly after a high rate of current decay do cause rapid clean-up.

Circuit cushioning or snubbing, in which a series resistor and capacitor are connected across each thyratron to retard the rate with which inverse voltage is applied, as along *ABCDEFG*, Figure 2, has been used with varying degrees of success. At best, the added components represent an increased cost to the panel and allowance must be made for dissipating considerable power loss in the cushion components.

From the standpoint of tube design, it was felt that improvements could be made over the conventional thyratron design whereby the problem of gas clean-up could be minimized. By conventional thyratron design is meant a design, Figure 3, in which a disk-shaped or cup-shaped anode is mounted on the end of a lead sealed to the top of the bulb; the grid and cathode are mounted from the cathode stem leaving a grid-anode separation of from one-quarter to three-quarters of an inch.

One attack on the clean-up problem might be merely to increase the gas pressure in a conventional design thyratron several fold on the basis that saturation would certainly occur before the gas pressure was reduced to the point where tube characteristics were impaired. A significant law by Paschen (Figure 4), however shows that there is a definite relation between the product of gas or vapor pressure p and effective electrode spacing d and the maximum potential that may be applied between electrodes without causing ionization or breakdown.*,[8]

For a thyratron, this means that a large increase in gas pressure would reduce the maximum controllable anode voltage. Anode voltages in excess of those governed by the law would cause ionization from anode to grid or around the outside of the grid to the cathode shielding, the cold discharge producing enough ions to cause the thyratron to pick up or conduct in normal fashion. A further complication results from the fact that the d in Paschen's law is not necessarily the direct spacing between the anode and the nearest electrode. The actual effective distance d may be equal to the length of a curved path, crossing equal potential lines at right angles, between any part of the anode to any part of the other elements. Hence, it is the "long-path" discharge that limits the maximum controllable anode voltage of a thyratron. The actual length of a "long-path" is vague and influenced by such irregular factors as the point of origin, the shape of the bulb and internal tube structure, nature of anode surface, and constriction along the path. For this reason it is impossible to calculate the absolute maximum controllable anode voltage for a given pressure and tube geometry.

While Paschen's law is not generally helpful for making absolute calculations it is invaluable in the relative sense.

Several types of gas tubes of conventional design with an anode voltage rating of 500 volts are available. These are filled with about 100 microns of gas initially. The voltage rating is too low for many motor control applications. Other gas tubes commonly employed in motor control and having voltage ratings of 750–1,000 volts have been initially loaded with about 50 microns of gas. It is apparent that if a conventional design were to be used at the desired 1,500 volt rating the initial gas pressure would have to be so low that any gas clean-up could not be tolerated.

Paschen's law indicates that in order to establish a 1,500 volt anode voltage rating and still assure loading the tube with the maximum amount of gas, the electrode spacing should be made as small as possible and the anode completely shielded, except for an opening to the control grid, to prevent spurious long-path discharge.

* At present, there is no known data for Paschen's law in terms of Xenon. However, it is believed that a curve for Xenon would have the same general shape as that for mercury.

Tube Construction

In order to make possible this close electrode spacing, a method of stack mounting the tube elements and spacing them by means of thin insulators was devised. Three equally spaced support rods welded to cathode stem leads and carrying tubular insulators, concentrically position all the parts and insulate them from one another. Referring to the cross section (Figure 5) the elements, starting with the first cup above the cathode, are shield, control grid, shield, anode, and shield. All cups below the anode have a circular opening at the center with the exception of the control grid. Several narrow rectangular openings have been punched out of the center of the control grid cup to provide the tube with a steep control characteristic. The control grid and shields are electrically connected to two different support rods. The grid connection is brought out through the base while the shield connection is made to the midpoint of a center tapped resistor connected across the filament leads inside the base. In this way the shields maintain the same potential as the anode and grid return which is also at the electrical center of the filament circuit by virtue of its connection to the center tap of the filament transformer.

Though the number of parts in the stack is large, the parts are mounted together easily and care must be taken only to position correctly the bottom eyelets on the three support rods and place the parts in their proper sequence on the stack. The relation of the length of the tubular insulators to the height of the stack is such that the top surface of the top bead insulators will always be slightly higher than the top of the tubular insulator. Thus when the top eyelets are pressed down and welded in place any slack is taken up and the whole assembly becomes a rigid structure. Since the anode is an integral member of the stack, the grid-anode structure becomes anchored to the top of the bulb when the anode seal is made. Small sputter cups which enclose and shield the bead insulators are located at strategic points in the stack where it is necessary to guard against electrical leakage paths which would be formed on the insulators by deposition of evaporated cathode materials.

The fact that the tube structure, with the exception of the light cathode, is supported from both ends of the bulb provides a rigid assembly which withstands high accelerations in vibration and shock.

It can be seen from Figure 5 that the top of the anode and the anode lead are well shielded and closed off from the top portion of the tube so that a long-path discharge cannot occur between some point at high anode potential and another point at low potential. Were it not for the shield over the anode, ionization could strike over a looped path centimeters in length between the top of the anode and the top of one of the support rods at or near cathode potential. The effective electrode spacing d then would be centimeters in length. Such a discharge would be more likely to occur than an even longer one from the top of the anode to the control grid or cathode because of the constriction between the bulb and the shield at the side of the anode.

Looking at the bottom anode surface, one sees that the longest effective path d between anode and any low potential element corresponds to the distance from the center of the anode to the center of the control grid, and that this d is millimeters in length. It is apparent that this latter value of d is the largest and the governing one in the *GL-5545* and may be considered as the effective electrode spacing between the anode and a low-potential element (in this case the control grid). The fact that the effective electrode spacing d in the *GL-5545* may be measured in millimeters rather than in centimeters, as is the case with conventional type thyratrons, permits the loading pressure p to be as high as 100 microns and the product pd still small enough to permit a 1,500 volt anode voltage rating.

In addition to the advantage of the high-gas pressure contained in the *GL-5545*, the thorough shielding of the anode and small electrode spacing are further instrumental in reducing gas clean-up. After current commutation, when the anode voltage may be highly negative, and there is still residual ionization in the tube, the ions bombarding the anode are drawn from the small column of ions beneath the anode. The height of this column is equal to the distance between anode and control grid and its diameter is equal to the diameter of the opening in the shield directly below the anode. For a given current the total number of ions in the column is a function of the distance between the grid and anode, and therefore the small grid-anode spacing holds ion bombardment of the anode to a minimum. Ions in other regions of the tube collect on the surfaces at cathode potential, on the control grid, or on the bulb walls. By contrast, all of the anode surface in the conventional design, Figure 3, is available for ion bombardment, while the larger grid-anode spacing results in more ions being available for bombardment.

Because the *GL-5545* is a shielded grid

Figure 2 (A). Biphase half-wave rectifier circuit

Figure 2 (B). Voltage across one tube

Figure 3 (right). Tube FG-178-A

triode, it possesses some of the advantages associated with dual-grid thyratrons such as low grid-to-anode capacitance and high grid-to-cathode capacitance. This capacitance relation offers increased tube stability in that transients or disturbances in the anode voltage supply are less likely to be coupled to the grid in sufficient magnitude to cause spurious triggering of the tube. Another phenomenon known as constriction is less likely to cause damage to grid circuits when a shielded-grid thyratron is used. Constriction occurs only in tubes in which there is low gas or vapor pressure resulting in ion starvation and the inability of the tube to carry high peak current. When constriction occurs, the current through the tube ceases abruptly despite the fact that the anode supply voltage may be highly positive.[8] The anode voltage will not only build up to the supply voltage, but because of the rapid rate of change of current through the transformer, the anode voltage may assume a value many times the actual supply voltage. In the event of constriction, the maximum voltage appearing at the grid is $C_{pa}E_b/C_{pa}+C_{gk}$, where C_{pa} is grid-anode capacitance, C_{gk} is grid cathode capacitance, and E_b is the peak voltage appearing at the anode. In circuits employing thyratrons in which the control grid is not shielded, high-voltage wave fronts of this type capacitively coupled to the grid have caused failures of low-voltage components in the grid circuit. The fact that the *GL-5545* ratio of anode-grid capacitance to grid-cathode capacitance is low offers maximum protection against component failures in grid circuits in the event of constriction.

Tests

Life tests have been conducted on *GL-5545*'s in typical motor controls under two different sets of conditions as shown in Table I. In both tests two tubes were used in a biphase half-wave rectifier circuit with an inductive load, and the firing angles were adjusted so that the load current was continuous.

Table I. GL-5545 Test Results

	Per Tube Values	Test 1	Test 2
A.	Average current	2.5	4.75
B.	Peak current	5	9.5
C.	Peak inverse voltage	1,000	1,000
D.	Rate of rise of inverse voltage in volts per microsecond	10	5
E.	Rate of current decay in amperes per microsecond	0.15	0.15
F.	Product of (D) and (E)	1.5	7.5–15
G.	Tube life hours	4,000	3,500

In the first test, the rate of rise of inverse voltage was conditioned by cushioning circuits. In the second test, cushioning circuits were eliminated, and the rate of rise of inverse voltage was extremely high.

For comparison, the same tests were repeated on established gas tubes of older design which were known to have long life in circuits presenting resistive loads. The tube ratings were such that the maximum permissible product of rate of rise of inverse voltage and rate of current decay (in volts and amperes per microsecond respectively) was 0.66. Tests 1 and 2 then yielded tube lives of 300 and 250 hours respectively.

Further tests are being conducted to determine the maximum product of rate of rise of inverse voltage and rate of current decay that the *GL-5545* will tolerate. It appears that little cushioning if any will be needed for motor circuits.

Other Tubes in Line

Present plans call for the development of other gas-filled tubes suitable for motor-control work ranging in average current ratings from 1/2 ampere to 12.5 amperes. Although the physical tube size will be

Figure 4. Paschen's Law

changed in relation to the current rating, the internal tube structure will be similar so that the desirable features of the *GL-5545* will be retained.

Several 3.2 ampere thyratrons, *GL-5544* employing a 30-watt filament are undergoing tests at the present time. In these tubes the bulb diameter and the grid-anode structure are identical to those of the *GL-5545* and the height of the bulb has been reduced one inch.

Gas-and-mercury combination tubes

Figure 5. Cross-section of tube GL-5545

are those which contain a charge of both mercury and gas. These tubes will conduct on the charge of gas during warm-up periods, but as the mercury temperature is increased, the mercury takes over and carries the load. Hence, combination tubes combine the advantages of mercury-filled tubes with the quick heating associated with gas-filled tubes. Because the summation of warm-up periods in a tube is a small fraction of tube life, only a small charge of gas is needed. Low-gas pressures of 50 or fewer microns have permitted anode voltage ratings in excess of 1,000 volts for conventional design thyratrons.

Gas-and-mercury combination tubes have been made in the 3.2 ampere rating. The electrode structure is identical to that of the 3.2 ampere gas tube, but the structure has been placed in the taller *GL-5545* bulb and a heat shield added below the filament. The larger ratio of bulb area to watts dissipated and the heat shield allow the condensed mercury temperature to fall within acceptable limits.

Combination tubes, however, are limited as are mercury tubes in the maximum ambient temperature rating and must be larger in size than gas-filled tubes having the same current rating. In the light of operating data for the gas tubes of this new design, it would appear that there is little to be gained by the use of combination gas-and-mercury tubes.

Conclusion

Tests have established the value of combatting gas clean-up and extending anode voltage ratings in gas-filled thyratrons by employing a design in which the elements are closely spaced and the anode well shielded. Excessive clean-up is eliminated by a combination of the following factors:

1. The tube is filled with a generous gas supply.
2. Minimum area of the anode is exposed to ion bombardment.
3. Ion population is small.

Results of tests to date indicate that tubes of the new design will operate with freedom from many of the limitations of older design gas-filled thyratrons.

Discussion

Hubert H. Wittenberg (Radio Corporation of America, Lancaster, Pa.): Although the *GL-5545* is rated at 6.4 amperes average and 80 amperes peak, life test results are given only for 4.75 amperes average and 9.5 amperes peak. What life is obtained at full rated peak and average currents? Gas clean-up can occur during the ionization period as well as after the conduction cycle. Witness the uses of gas thyratrons in radar service and in sweep oscillators where the inverse voltage is negligible.

At what temperature does the anode of the *GL-5545* operate? The enclosed structure should result in a high anode temperature. The low gas clean-up may result from the high-anode temperature as well as the restricted anode area available for ion bombardment.

Has grid emission been a problem in the development of the *GL-5545*? What is the grid emission in terms of shift of the control characteristic with small and large grid resistors at rated average anode current?

Why is the shield grid connected to the center tap of a resistor in the base of the *GL-5545*?

D. V. Edwards (Electrons, Incorporated, Newark, N. J.): Having had experience with a line of tubes similar in ratings and cathode coatings to those discussed by Coolidge, I can confirm his conclusions that much improvement can be made in the commutation factor rating and voltage rating of gas filled tubes by modifications of the tube design and that commutation ratings of latest designs are approaching the point where cushioning is no longer required.

Our experience would justify going beyond the author's statement in regard to gas clean-up. In the two years since commutation ratings for gas-filled tubes were proposed, gas clean-up has been eliminated completely where the commutating duty imposed by the circuit was within tube rating.

In comparing tube designs, we have not been able to get reliable information from accelerated life tests by operating tubes at above rated commutation duty and comparing the lives obtained. The reason for this becomes apparent when the lives obtained within a particular tube design are plotted against the commutating duty applied by a series of circuits of increasing duty.

This curve has such a sharp knee that individual tube variations mask the effect of variation in tube design when tests are run in the region beyond correct commutation rating.

The interpretation of the author's data on the type *GL-5545* given in Table I of the paper would be facilitated by knowing how failure occurred in test 1 and whether detectable gas pressure change had occurred.

The author attaches more importance to the effect of loading pressure as a means of avoiding gas clean-up than experience with type *C6J* would indicate. This tube, a 1937 design, carries a loading pressure higher than any of the tubes listed in the paper, yet has a slightly lower rated commutation factor whereas the *C6M* with the same loading pressure as the *C6J* has a higher commutation factor.

A. W. Coolidge, Jr.: Wittenberg's questions are answered below in the order in which they were presented in the discussion.

The average life of the *GL-5545* when operated at 6.4 amperes average and 80 amperes peak is 3,000 hours. The writer concurs that clean-up can occur during the ionization period as well as after the conduction period. Tests indicate, however, that clean-up during conduction is negligible compared to that which occurs after conduction when the product of the rate of rise of inverse voltage and the rate of current decay is high.

When the *GL-5545* is operating at full load the anode temperature is about 900 degrees centigrade. The high anode temperature is not a cause for the low gas clean-up since the tubes of conventional design which were run under the conditions of Table I and which suffered short life because of gas clean-up operated with anode temperatures only slightly lower than those of the *GL-5545*.

Grid emission was a serious problem in the development of the *GL-5545* until the cathode coating using the nickel sesquioxide was substituted for the conventional barium oxide coating. As mentioned in the paper the nickelplate coating is metallic, tenacious, and well bonded to the base metal, and hence there is less tendency for the coating to be sputtered and deposited on the control grid. The maximum grid emission current in a *GL-5545* during normal operation should not exceed ten microamperes.

The shield grid is connected to the center tap of a resistor in the base so that it is held at the potential of the anode return. Thus, the tube has the external connections of a triode and the shield grid does not cause spurious shifts in the control characteristic as it might were it left floating.

At the outset, the writer wishes to clarify a term in Edwards' discussion which was not introduced in the paper. The term, "commutation factor" has been applied to the product of the rate of rise of inverse voltage in volts per microsecond and the rate of current decay in amperes per microsecond. Its usage is gaining favor, and it is a convenient term in the discussion of gas cleanup.

With reference to the second paragraph of Edwards' discussion, the author concurs that gas clean-up has been sufficiently reduced by tube or circuit design so that it is no longer a factor in the life of the tube when the tube is used within the rated commutation factor. By the use of a snubber circuit as described in the paper the commutation factor can be limited to less than the maximum rated commutation factor for any tube. The snubber components do, however, represent added cost, require extra space, and perhaps of more importance there is a continuous power loss during operation, the size of the loss being dependent on the amount of snubbing required. The *GL-5545* described in the paper has a rated commutation factor more than ten times higher than that for a tube of conventional design and of otherwise equal rating. This means that the *GL-5545* requires much less snubbing than tubes of conventional design.

Edwards has found a sharp knee in the curve of tube life versus commutation factor for a particular design. The tests on the tubes of conventional design described in the paper would appear to support this as it is known that these tubes have long lives when the commutation factor is below 0.66. Yet, when the commutation factor was increased to 1.5 in test 1 and about 10 in test 2, the tube life was only 300 and 250 hours respectively.

Another test which has been run since the paper was written and in which the commutation factor was 40 yielded a tube life of 300 hours. This would indicate that there is a critical threshold value for the commutation factor below which tube life is quite satisfactory, and above which the life is short. As the commutation factor is increased to higher values beyond the threshold value, the tube life is not materially reduced.

The knee for the *GL-5545* curve has not

been determined as yet as all life tests in which the commutation factor has varied from 1.5 to 40 have resulted in no excessive gas clean-up or short life.

The two *GL-5545*'s described in test 1 in the paper, failed at approximately 4,000 hours because of low cathode emission. One of the tubes was damaged because of a poor socket contact connection to a filament pin on the tube. Since pressure gauges were not built into these tubes, the actual pressure change that occurred during life is not known. There was not, however, sufficient clean-up to cause the tube characteristics to shift outside of the published specifications.

Despite Edwards' comments in the last paragraph of his discussion, it is felt that in order to assure the highest degree of freedom from gas clean-up it is important to load the tube initially with as high a gas pressure as possible. It is not stated in the paper that the high gas pressure of the *GL-5545* is solely responsible for the increased resistance to gas clean-up that the tube exhibits over tubes of conventional design. As stated in the conclusion excessive gas clean-up is eliminated because of a combination of three factors of which the loading pressure is one.

If a tube of conventional design is loaded with a generous gas supply, and is subject to clean-up at low commutation factors, it is the writer's belief that the reason may lie in the fact that the second and third factors listed in the conclusion of the paper are lacking. In other words, the reason may be attributed to the fact that the anode is exposed and the volume of ionization is large.

A New Line of Oil-Filled Apparatus Bushings

B. N. BOWERS
ASSOCIATE AIEE

D. L. JOHNSTON
ASSOCIATE AIEE

FOR 32 years, oil-filled bushings have been applied to transformers and oil circuit breakers. Electrically and mechanically, the performance of these bushings has been remarkably good. However, because of recent trends in the design of electrical apparatus, some features of the bushings have become outmoded and it has been necessary to redesign the oil-filled bushing to obtain improvements which will meet the requirements of modern apparatus.

Chief among these requirements are hermetic sealing, low-cost maintenance, mechanical strength, and reduction in size and weight. To meet these needs, and in addition to provide for ease of installation and storage, the new bushing was designed.

This bushing has been in production for approximately two years for transformer and oil circuit breaker applications and is described in the following paragraphs.

Advantages of the New Construction

The hermetic sealed construction, accomplished by center-clamping and by the use of synthetic rubber gaskets prevents deterioration of the internal insulation of the bushing by moisture or by oxidation, thus eliminating the principal weakness of the older bushings. The rubber gaskets are oilproof and waterproof and retain their resiliency under all expected conditions of service.

The sealed construction has been thoroughly service-tested in liquid-filled, solid core bushings in the moderate voltage range. Approximately 100,000 bushings of this type have been placed in service in apparatus in the last 16 years and their very satisfactory service record is due largely to the use of synthetic rubber gaskets which provide a reliable gas and oil-tight seal.

The hermetic sealing of the new bushing also eliminates the need for costly maintenance which in the case of the old bushing meant renewing the oil or complete disassembly to clean and dry the internal insulation. Since the new bushing is completely sealed, the initial high dielectric strength is maintained through the years of service without costly operations on the internal insulation. In general, inspection of the oil level gauge and cleaning of the porcelain shell periodically are desirable.

High mechanical strength is obtained by center-clamping and the new bushings have demonstrated their ability to withstand without damage severe mechanical loadings under static conditions and also under interrupting tests applied to oil circuit breakers.

Reduction in diameter has been obtained by the center-clamped construction which requires no cemented-on clamping rings and by adjustment of internal insulation stresses to obtain maximum efficiency of the dielectric structure. The reduced diameter permits the use of smaller bushing-type current transformers, the elimination of mounting adapters, and less complicated apparatus covers, all of which are favorable to simplification of design and smaller apparatus.

Reduced weight which accompanies reduced size, facilitates packing for shipment, handling, and installation.

Installation of the new bushings requires no special equipment. Lifting eyes in the support flange provide means for attaching lifting cables.

The construction used in these bushings has inherently low power factor and thereby is particularly suited to power factor testing when desired for checking the condition of the bushing.

Application

The new bushing is available, with or without the capacitance tap feature, for application to transformers in voltage ratings from 92 to 360 kv, and to oil circuit breakers in ratings from 115 to 196 kv.

Standard bushings for oil circuit breakers are equipped with the capacitance tap which is also available for transformer bushings.

Bushings in ratings from 115 to 230 kv have mounting flanges which are interchangeable with the superseded bushings. The elimination of the bottom clamping ring has permitted shortening the bushings approximately 3 inches. For replacements in oil circuit breakers, a suitable adapter can be provided to compensate for the shortened length, and thereby readily adapt the new bushings to the older circuit breakers.

Bushings in the foregoing ratings for transformers which have detachable cable terminal parts may be interchanged with the old bushings having the same ground sleeve length, since the terminal studs which are brazed to the transformer leads are interchangeable. Differences in height between the old and new bushings may in some instances require changing the length of the cable leads.

Typical and special applications of the new bushing are shown in Figures 1, 2, 3, and 4.

A comparison of the sizes of the old and the superseding new bushings for oil circuit breakers is given in Table I. Standard bushings in ratings 92 to 230 kv are shown in Table II.

Paper 48-174, recommended by the AIEE switchgear and transformer committees and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, April 28–30, 1948, New Haven, Conn. Manuscript submitted February 16, 1948; made available for printing March 8, 1948.

B. N. Bowers and D. L. Johnston are both with the high voltage bushing engineering division of the General Electric Company, Pittsfield, Mass.

Figure 2. 360 kv capacitance bushing for transformer service

Figure 3 (right). 360 kv (1,300 kv, basic insulation level) capacitance bushing with built-in current transformers for outdoor switchgear

General Description

Principal features of the new bushing are:

1. Bushing is center-clamped, placing porcelain parts under compression, in which stress porcelain is strongest.

2. Gaskets at ends of porcelain shells are confined in recesses of proper depth to insure pressure-tight joints without metal-to-porcelain contact.

3. High-pressure multicoil spring assembly maintains a safe pressure on gasketed joints under all conditions of operation.

4. All gaskets are of synthetic rubber which is oilproof and waterproof, and retains its resiliency under all expected conditions of service.

5. Internal insulation is of oil-permeable barriers and oil ducts in combination, insuring high dielectric strength under testing and operating voltages.

6. Excepting the dome, all castings in ratings 115 to 161 kv have been eliminated. High strength brass forgings have replaced the castings in most nonmagnetic parts.

Figure 5 shows a cross-sectional outline of a 138-kv capacitance bushing which is described herein.

The center tube of the bushing is of high-strength copper, threaded and sweated into the forged brass bottom washer which has a side drain hole sealed by a threaded plug and copper-asbestos gasket.

An electrode, consisting of an aluminum tube insulated with adhesive-bonded oil-permeable paper is assembled down over the center tube and held in position by a brass collar locked to the center tube by set-screws. A spiral contact spring of phosphor-bronze insures a permanent connection between the center tube and electrode.

The support is of fabricated steel, electric-welded. In general the mounting flange of circuit breaker bushings is overhung to provide a rocker-type mounting joint and for transformer application the flange is flat with a gasket recess 1/8 inch deep. Interchangeability between old and new bushings is not impaired by these differences in the transformers and circuit breaker bushing flanges. However, it is not practical to adapt old bushings to oil circuit breakers originally equipped with new bushings.

Transformer bushings are equipped with detachable cable (draw lead) accessories. The bottom washer is of smooth contour with no sharp projections.

Oil circuit breaker bushings use the center tube for the conductor. The bottom washer has a spherical contact surface which permits ready adjustment of the circuit breaker interrupter which is flanged-clamped to the bottom washer of the bushing.

The top and bottom porcelain shells are of high quality, 1-piece porcelain with no gasketed joints (except in the 2-piece top shells above 230 kv), uniformly glazed on the outside surfaces and with accurately ground gasket surfaces at the ends. Both shells are assembled against flanges at the ends of the support and are held in position by center-clamping of the structural parts of the bushing. Gaskets at the ends of the shells are confined in recesses in the metal flanges. Bushings in ratings up to 161 kv have gaskets 3/16 inch thick, confined in recesses 5/64 inch deep. Gaskets for bushings of higher voltage ratings are 1/4 inch thick.

The insulating cylinders are of adhesive-bonded oil-permeable paper held in position by T-headed spacing blocks of kiln-dried maple. The spacing blocks are located at the top of each cylinder and are locked into grooves cut into the surface of the next smaller cylinder or electrode insulation. The ducts alternating with the cylinders are filled with oil. Each of the insulation cylinders has a nonmetallic conducting rescon equalizer embedded in the cylinder, and proportioned to provide safe internal voltage gradients and, in combination with the terminal and ground shields, suitable voltage distribution in the external dielectric fields of the porcelain shells. The terminal shield is located inside of the top end of the top shell. Actually, no ground shield is built into the bushing. The ground shield function is, however, performed by a concentric nonmetallic conducting rescon plate embedded in the largest diameter insulating cylinder and grounded through a tap which is connected to the support. This conducting plate extends a few inches above and below the ground sleeve of the support in an assembled bushing.

Figure 4. 92-kv bushing with expansion chamber integral with support, for wall entrance service

Figure 6 shows the details of the top end of the 138-kv bushing. At the top end of the bushing, an expansion chamber or dome of heat-treated high-strength aluminum provides for change in oil volume due to temperature variation. The expansion space of 20 per cent of the oil volume in the bushing limits the maximum pressure in operation to a moderate value. A magnetic gauge in one side of the dome indicates the level of the oil in the bushing and is easily read from the ground under most conditions of operation. The dome is amply protected from weather by a special baked-on finish. The filling hole in the dome is sealed by a threaded metal plug and a confined synthetic rubber gasket. A larger threaded hole at the outside of the dome provides for attaching a fixture which permits assembling the sealing plug and gasket with nitrogen pressure in the bushing. After sealing, a protective plug is assembled in the outer threaded hole.

The spring assembly at the top end of the bushing compensates for thermal expansion of the structural parts, thereby maintaining safe clamping force under all conditions of operation. The spring assembly consists of many small steel coil springs arranged concentrically around the center tube and enclosed in a toroidal diaphragm of spun copper. Forged brass washers at the ends of the springs prevent distortion of the diaphragm.

The forged brass cover which is threaded to the center tube is tightened down against the spring assembly to apply the required center-clamping force to the bushing structure and to all major gasketed joints. Synthetic rubber gaskets on top and bottom sides of the diaphragm are confined in recesses in the adjacent parts. Metal-to-metal contact is made from dome-to-diaphragm-to-cover at the inner edge of each gasket recess to insure permanent electrical contact. A small threaded synthetic rubber gasket, compressed by a phosphor-bronze spring forms a seal which prevents leakage of oil between the threads of the cover and center tube.

Bushings which are equipped with detachable cable accessories have a forged brass cap which screws into the cover, a forged copper terminal stud held into the cap by a pin, and a forged brass terminal cap which screws down over the terminal stud against the cap. Each joint below the cap and terminal cap is sealed by a synthetic rubber gasket confined in a recess. Bushings which use the center tube as a conductor have a terminal cap which screws into the cover and is sealed to the cover by a synthetic rubber gasket as described before.

In bushings equipped with the capacitance tap feature, details of which are shown in Figure 7, the outer insulation cylinder which is known as the capacitance cylinder is of resin-bonded paper and has two concentric, nonmetallic conducting plates of rescon which form the tap and the ground plates respectively. These plates extend from a few inches above the support sleeve down to a few inches below it. A copper electrode 0.005 inch thick and 2 inches wide is wound into the cylinder in contact with each rescon plate to provide means for making contact for tap and ground connections. A spring contact is made with the inner tap plate, through a large hole in the outer ground plate which has a soldered contact and is grounded to the support by a copper braid. The tap plate has a nominal open circuit potential of 3,600 volts to ground.

A capacitance tap chamber just above the mounting flange of the support encloses a small bushing of molded insulation with a spring contact at the inner end which makes contact with the inner plate of the capacitance cylinder. The outer end of this bushing is normally grounded by means of the cap but for operation in connection with a potential device, the cap is removed and replaced by a potential device cable connection, the chamber being filled with a viscous insulating compound through a fill hole in the top and sealed by a pipe plug for this condition of operation. A round section gasket of synthetic rubber seals the joint between the tap chamber and the cap or potential device connection.

Table I. Comparison of Old and Superseding New Bushings Rated 1,200 Amperes for Oil Circuit Breakers

Rating	Old, Inches	New, Inches
115 kv		
Live metal, top end, diameter	10.8	10.8
Live metal, bottom end, diameter	8.8	7.6
Height above flange	63.0	57.1
Length below flange	44.7	41.6
Oil content, gallons	17.5	8
Maximum diameter below flange	14.5	10.8
138 kv		
Live metal, top end, diameter	10.8	10.8
Live metal, bottom end, diameter	8.8	7.6
Height above flange	70.4	66.0
Length below flange	48.4	45.3
Oil content, gallons	26.5	14.5
Maximum diameter below flange	17.0	12.8
161 kv		
Live metal, top end, diameter	10.8	12.2
Live metal, bottom end, diameter	8.8	7.6
Height above flange	77.0	74.8
Length below flange	52.0	48.8
Oil content, gallons	42.3	23.3
Maximum diameter below flange	19.1	14.8
196 kv		
Live metal, top end, diameter	13.5	15
Live metal, bottom end, diameter	15.0	13.7
Height above flange	92.6	112.4
Length below flange	67.3	67.7
Oil content, gallons	91	55
Maximum diameter below flange	24.5	18.8

Assembly

In assembling the bushing, the cover is screwed down against the spring assembly.

† Oil circuit breaker
‡ Detachable

The torque necessary to give the correct value of center-clamping force is applied to the cover at assembly. The gap between the cover flange and the dome is also used as an approximate indication of the applied center-clamping force.

The assembled bushing is subjected to a vacuum treatment at a pressure of less than 1,000 microns of mercury at 110 degrees centigrade. It is then allowed to cool and is filled through the drain hole in the bottom washer with degasified insulating oil of controlled high quality. An oil pressure test of 20 pounds per square inch is applied for 15 minutes and inspection is then made for leakage. Although the vacuum treatment is sufficient to reveal any leakage, the pressure test is a final confirmation of pressure-tightness. After the oil level has been adjusted, the bushing is sealed pressure-tight through the filling hole in the dome with a cushion of dry nitrogen gas at ten pounds per square inch.

Test Data

Electrical tests on one 138-kv bushing gave the following results:

Power factor, 0.96 per cent
Capacitance, 252 $\mu\mu f$

60 Cycle
Dry flashover, 422 kv
Dry withstand (1 minute), 335 kv

Impulse
Positive critical flashover, 749 kv
Positive withstand, 650 kv
Negative critical flashover, 757 kv
Positive steep wave, flashover, 1,090 kv*
Negative steep wave, flashover, 1,075 kv*

In an effort to determine the ultimate dielectric strength a 138-kv bushing was subjected to the following 60-cycle tests.

1. Fifty flashovers, each followed immediately by a 1-minute test of 335 kv, were applied with 1-minute intervals. The first flashover was 386 kv—the fiftieth, 400 kv.

2. The bushing was subjected to the specified standard 1-minute value of 335 kv for one hour with no indication of distress.

3. In order to apply higher voltage stresses to the internal insulation, the bushing was immersed in the oil in the test tank to the third petticoat of the top shell above the support and withstood ten snap-overs to the edge of the test tank at voltages up to 400 kv and three 1-minute withstand tests at 375 kv.

* At rate of approximately 1,000 kv per microsecond.

Power factor values before and after the tests were 0.68 and 0.73 per cent, respectively, indicating no deterioration of insulation. Examination of the internal insulation of the bushing following the tests revealed no evidence of impairment.

Routine and design electrical tests on one 230-kv capacitance bushing for transformer service gave the following results:

Routine
Power factor—0.78 per cent, 60-cycle flashover—621 kv
Capacitance: 410 $\mu\mu f$, 60-cycle 1-minute withstand—545 kv
Tap voltage: 3,420 volts

Design
60 cycle, wet flashover—503 kv
wet 10 second withstand—445 kv
Impulse, positive critical flashover—1,130 kv
Positive withstand—1,050 kv
Negative critical flashover—1,340 kv
Negative withstand—1,050 kv

Conclusion

This paper has described a new line of high voltage bushings in voltage ratings from 92 kv to 360 kv which meet AIEE and the National Electrical Manufacturer's Association Standards and which are applicable to transformers and oil circuit breakers as well as to other types of service. These bushings were designed to meet the needs of modern apparatus and are constructed to give reliable service with a minimum of maintenance.

At the present time, standardization and consequent reduction in the number of special designs for a given voltage rating is under way. It is anticipated that the new bushings can be applied with a minimum of designs and thus contribute to this trend. In the broad interest of standardization and its far-reaching benefits the authors recommend that consideration be given to the elimination of special features wherever possible.

Figure 7. Cross-sectional view of capacitance tap feature

Discussion

H. L. Cole (Westinghouse Electric Corporation, Sharon, Pa.): Bowers and Johnston have described the design and development of a new and improved oil-filled bushing which incorporates features well recognized by most engineers as contributing to long life and low maintenance. A redesign of a standard line of high-voltage apparatus bushings, requiring new porcelain casings and a new type of construction, is a major development project. The authors are to be commended for presenting this new equipment to the industry.

The new General Electric bushing embodies many of the principles of the Westinghouse condenser type described in an Institute paper[1] five years ago. I would like to discuss briefly the design features emphasized in the present paper.

Hermetic sealing of oil-filled apparatus, with elimination of breathing, has been advocated by the Westinghouse Electric Corporation for years, not only for bushings but for high-voltage power transformers as well.

The use of the capacitor principle in bushing design makes it possible to obtain maximum efficiency of the dielectric structure as pointed out by the authors, and the internal volume of liquid is small enough to operate the bushing over wide ranges of temperature with a sealed cap of reasonable size and proportion.

End clamping of porcelains, with spring pressure on the porcelain gaskets, eliminates the need for more expensive and less effective cemented-on hardware. This construction has been proved by 15 years of centering clamping on our large condenser bushings. The steel springs in the cap not only provide for gasket pressure under changing temperatures but, when designed with ample pressures, will permit shipment of the bushing in a horizontal position with little or no additional support to the porcelains.

Oil-permeable paper is used as the major insulation in the new bushing. The writer questions the need of oil ducts in a construction having conducting layers for equalizing gradients in the dielectric and in which the over-all power factor is less than one per cent. In our opinion, the most efficient use of the paper is made when there is little or no adhesive bond, no oil ducts, ample vacuum treatment to remove air and moisture from the paper, and thorough impregnation with degassed oil. At various times, during our condenser bushing developments, we have considered the use of oil ducts through the condenser but have never adopted them.

Instead, there have been improvements in materials to give lower power factors and better control of processes to obtain uniform quality of insulation throughout the core of the bushing. Exhaustive life tests have been made, with assembled bushings entirely immersed in 90 degrees centigrade oil and operated for days at voltages in excess of the standard 60-cycle withstand values, to prove that oil impregnated paper condenser bushings without adhesive bond on the active insulation and without oil ducts through the insulation are electrically and thermally stable. Oil ducts, when used in condenser bushings, add relatively little to the electrical strength because most of the strength is obtained from the solid insulation. Omission of the oil ducts and a more generous use of the "conducting equalizer layers" would permit even smaller bushing diameters than those described in the paper. The bushing would have a higher capacitance, and potential devices with larger volt-ampere burdens would be permissible.

Magnetic oil gauges, used on condenser bushings and other liquid-filled electrical apparatus for many years, have proved their superiority to the old fashioned glass oil gauge. A magnetic gauge with alloy magnets of high permanence, properly shielded to prevent demagnetization when the bushing is subjected to heavy short circuit currents, eliminates the possibility of oil deterioration by sunlight and permits better visibility of the oil level.

The authors state that porcelain up to and including 230 kv is one piece. Does that mean that the porcelain is made in sections which are then united by means of a fired glaze?

In closing this discussion, the writer wishes to compliment the authors in presenting a clear and concise description of a new and modern bushing.

Reference

1. Oil-Impregnated Paper High-Voltage Condenser Bushings for Circuit Breakers and Transformers, H. J. Lingal, H. L. Cole, T. R. Watts. AIEE Transactions, volume 62, 1943, June section, pages 289–74.

B. N. Bowers: We are glad to have H. L. Cole's able discussion of the paper, which in many ways emphasizes the important features incorporated in the new bushings. Since one of the features discussed, namely, "hermetic sealing" involves the gasket material, it seems desirable to comment briefly on this subject.

Composition cork gaskets had been used by the industry up until 1932 for sealing joints of oil-filled apparatus and various adhesives were used to cement the gaskets to metal and porcelain surfaces. For seals against oil pressure composition cork was generally satisfactory, but where oil was not in contact with and applying positive pressure to the joint, and particularly where a partial vacuum existed, considerable difficulty with leakage was experienced.

Recognizing the need for a gasket which would withstand pressure whether in contact with oil or not, General Electric pioneered in the development of gaskets of oil-resistant and moisture-resistant rubber and started to use them in moderate voltage bushings in 1932. Modern gaskets of synthetic rubber are manufactured to rigid specifications, the outgrowth of many years of experience which has made hermetic sealing possible. Cole inquires regarding the 1-piece porcelain shells which are used in ratings up to and including 230 kv. These shells are cast in sections, and turned all over to proper dimensions. The mating parts for the joints are accurately fitted to gauges. Each section is then placed one upon the other with the joints coated with a special fusing glaze. The shells are placed in the firing kiln and fired under accurately controlled temperature and atmospheric conditions. During this firing cycle the body of the porcelain is properly vitrified and the joints are fused or welded together by the glaze into one solid piece.

Each shell of this type is subjected to a transverse loading test, which assures ample mechanical strength.

Periodic tests to destruction are made as a means of controlling the factor of safety.

In a center-clamped structure such as is used in the new bushing the shells are placed in compressive stress only, which is a very favorable operating condition.

Electrical Properties of Ceramics as Influenced by Temperature

E. W. LINDSAY
ASSOCIATE AIEE

L. J. BERBERICH
FELLOW AIEE

Synopsis: Data on dielectric strength, resistivity and power factor are presented for a high-tension porcelain, a zircon porcelain and an alumina porcelain. Additional data on mica and fused silica taken from the literature are included for comparison purposes. The temperature range covered in the experimental work extends from 25 to 1000 degrees centigrade. When the logarithms of the dielectric strength, resistivity or power factor are plotted against the reciprocal of the absolute temperature, two straight lines of different slopes result in each case. The intersection of these two lines define a transition temperature between the disruptive and thermal regions of electric breakdown. An interesting feature of this investigation is the discovery that the transition temperatures as determined by the dielectric strength coincide approximately with those determined by resistivity or power factor. The transition temperature gives some indication of the maximum temperature beyond which the material should not be used in practice. Considerable advantage of zircon and alumina porcelains over high tension porcelain for high temperature applications are indicated. The data are discussed in the light of existing conduction and electric breakdown theories.

HIGH TENSION PORCELAIN, consisting largely of feldspar, clay and flint, has long been and still is one of the more important ceramics used in the electrical industry. It owes its unique position to the low cost of raw materials, ease of fabrication into wide variety of shapes and sizes, and uniform quality of the final product for application at ordinary temperatures and low frequencies. In recent years, and particularly during World War II, an increasing number of applications have arisen in which high dielectric strength at elevated temperatures is a prime requirement. In such applications, high voltage porcelain is not very satisfactory, for its dielectric strength begins to fall rather sharply with temperature above 100 degrees centigrade.

For the higher temperature applications, several special porcelains, among which are the zircon and alumina porcelains, have been developed. Both of these porcelains made their first appearance in spark plug applications, where resistance to thermal shock is perhaps just as important as high dielectric strength at elevated temperatures. During World War II, alumina dominated the important aircraft spark plug field and zircon found a number of specialized applications. Because of their superior electrical, mechanical, thermal and chemical properties, these porcelains are finding an increasing field of usefulness in both low and high frequency applications. Despite the importance of these porcelains, there appears to be very little data available on their dielectric behavior at elevated temperature. An investigation of the dielectric properties was, therefore, made on high tension, zircon and alumina porcelains over a wide range of temperature extending, in some cases, from 25 to 1,000 degrees centigrade. During the course of this work, a striking correlation between the dielectric strength, as influenced by temperature, and resistivity and power factor as influenced by temperature, was observed. A similar correlation was also found for mica and fused silica. The breakdown data and the theoretical significance of these correlations are discussed in some detail.

Samples and Testing Procedure

The samples consisted of simple, unglazed disks having diameters of 4 and 8 inches and thicknesses of 0.125 and 0.25 inch. The compositions as determined by chemical analysis of the completely vitrified bodies are given in Table I. The main crystalline constituents listed at the bottom of the table were determined by means of an X-ray spectrometer. It is well known and was substantiated by X-ray investigation that high tension porcelain consists of two crystalline phases, namely, quartz (SiO_2) and Mullite ($3Al_2O_3-2SiO_2$) with the former usually predominating. These two crystalline phases are bonded together by an alkaline aluminum silicate glass matrix. Zircon porcelain consists largely of oxides of zirconium, silicon, and calcium. It is produced by firing a mixture of zircon ($ZrO_2 \cdot SiO_2$), clay and alkaline earth oxide fluxes such as CaO. The fired body is largely crystalline zircon bonded by an alkaline earth aluminum silicate glass. Table I shows that the alumina body consists of a high percentage of alumina (Al_2O_3) with some silica (SiO_2) and smaller amounts of other oxides. This body is compounded from alumina and a small amount of clay or other fluxing material. X-ray investigation shows that the fired body is composed of α-alumina crystals bonded together by a small amount of alkaline earth glass.

Though all of the bodies may be considered as a glassy matrix in which the crystalline constituents are imbedded, it is difficult to determine the relative amounts of crystalline and amorphous or glassy phases. After examination of the X-ray patterns, however, it was estimated that high-tension porcelain has a rela-

Manuscript submitted February 13, 1948; made available for printing March 5, 1948.

E. W. LINDSAY is research engineer in the insulation department and L. J. BERBERICH is manager of the physical section in the insulation department, both of the Westinghouse Research Laboratories, East Pittsburgh, Pa.

The writers are indebted to C. F. Hill, R. Russell, Jr., C. N. Works and M. H. Welsh for their suggestions and assistance in carrying out the work described in this paper. The writers also wish to express their appreciation to G. I. Gilchrest of the Derry works of Westinghouse Electric Corporation for supplying samples of high tension and zircon porcelain bodies, and to H. W. Ryland of the Coors Porcelain Co., Golden, Colo., for supplying the experimental alumina porcelain bodies.

Table I. Composition of Various Porcelain Bodies

Constituent	Composition in Per Cent		
	High Tension Porcelain	Zircon Porcelain	Alumina* Porcelain
SiO_2	68.72	36.96	6.69
Al_2O_3	23.90	6.08	90.98
TiO_2	—	0.24	0.06
ZrO_2	—	49.72	—
Fe_2O_3	1.80	0.23	0.20
Na_2O+K_2O	3.46	0.13	0.21
CaO	0.25	6.48	1.08
MgO	0.12	0.14	0.66
Total	100.25	100.00	99.88
Total flux	5.83	6.75	1.95
Main crystalline constituent	Mullite ($3Al_2O_3 \cdot 2SiO_2$) Quartz (SiO_2)	Zircon ($ZrO_2 \cdot SiO_2$)	Alumina (α-Al_2O_3)

* This high alumina body is not commercially available.

tively high percentage of glass and that the alumina porcelain, on the other hand, has a low percentage of glass, while the zircon porcelain is intermediate. The glassy phase, particularly if it contains alkali metal oxides, has an important bearing on the electrical behavior of the body at higher temperatures.

Both a-c and d-c dielectric strength tests were made using the American Society for Testing Materials (ASTM) *D149-44* one-minute step-by-step testing procedure. This procedure produces results which have greater practical significance than is the case where the voltage is raised rapidly until failure occurs and it also allows time for the consummation of a thermal breakdown. It does have the disadvantage that the exact temperature of the sample at the time of failure is not known. At the higher temperatures, and, in particular, when the resistivity of the samples falls to less than 10^{10} ohm-centimeters, the sample temperature rises appreciably above the ambient temperature. Since this temperature rise is variable and usually unknown, only the ambient temperature at the time of breakdown was recorded. This does not affect the accuracy of the data appreciably except at the highest temperatures of test for each individual material.

Tests at temperatures about 125 degrees centigrade and below were made under oil using 1-inch diameter electrodes whose edges were rounded to 1/8-inch radius. A few tests were made in this same temperature range in air and the values were somewhat lower than those made under oil because the edge discharges were more severe in air. All of the tests above 125 degrees centigrade were made in the furnace shown in Figure 1. The electrodes are 3/4 inch in diameter and constructed of stainless steel because of the high temperatures involved. As the diagram shows, the inside of the furnace was lined with a grounded steel box of sufficient size that the field at the electrode would not be seriously affected. The furnace is equipped with automatic temperature control for temperatures up to 1,000 degrees centigrade.

Only a few breakdown tests were obtained in the temperature range of 150 degrees to 300 degrees centigrade on zircon and alumina bodies, because the breakdown strengths in this temperature region are still high enough to cause surface flashovers, especially in the case of the thicker and smaller diameter samples. Also, in this temperature range, the electrical discharges around the electrodes became so severe that punctures took place as much as one inch away from the edges of the electrodes. When the tests were made under oil, most of the punctures occurred at the edges of the electrodes, indicating that stress concentrations at the edges of the electrodes played a role. The results should, therefore, be interpreted as being representative of practical or apparent values rather than intrinsic values. Most of the punctures at the higher temperatures in the thermal breakdown region took place under the electrodes as might be expected.

The resistivity values were determined at low stresses (100–500 volts) by means of a general radio megohm bridge after one minute of electrification unless indicated otherwise. The electrodes consisted of fired-on silver films backed by 1/2-inch thick silver cylinders. The same electrode system was also used to measure the power factor at 100 kc. The equipment used to measure the power factor was a General Radio *716AS-1* bridge.

Experimental Results

The dielectric strength data as well as the resistivity data for the three ceramic bodies investigated are recorded in Figures 2, 3 and 4. All of the plotted points are the average of from three to ten individual breakdown tests. The scattering of the dielectric strength data was appreciable at the lower temperatures but this was negligibly small at the higher temperatures. The vertical scale on these graphs is logarithmic, and the horizontal is a reciprocal absolute temperature scale. These scales were chosen in plotting the dielectric strength and resistivity data since straight lines should be obtained, at least over limited temperature ranges. Referring first to the dielectric strength, it is observed that in all cases the data define, at least approximately, two straight lines. In the low temperature region, the dielectric strength is practically independent of temperature while above a certain temperature, which differs for each material and which will be referred to as the transition temperature, the dielectric strength falls rapidly with increased temperature. The region below the transition temperature is known as the disruptive or electric breakdown region while that above the transition temperature is known as the thermal breakdown region. Von Hippel and Maurer[1] report similar results for glass and show that such a behavior is to be expected of amorphous materials. In crystals the situation is somewhat different in that the d-c breakdown strength increases with temperature in the low temperature region until the transition temperature is reached when it decreases again, as is the case for amorphous materials.

Referring now to the resistivity data given in Figures 2, 3 and 4, it is observed that not only do these data also define two straight lines but that the transition temperatures for resistivity and dielectric strength approximately coincide. This coincidence of transition temperatures for resistivity and dielectric strength has not been observed previously, insofar as the writers know. This presents a new point of view which may help to throw further light on the nature of electric breakdown in solids.

This behavior holds not only for the ceramics investigated, but it was also found to hold for mica which is entirely crystalline and fused silica which is entirely amorphous. Data for muscovite mica reported by Hackett and Thomas[2] were replotted as shown in Figure 5. The smooth solid dielectric strength curves of Figure 5 represent the data as originally plotted on linear plot. The dashed lines were added to show that both the apparent or practical and the intrinsic or true dielectric strengths can be represented approximately by two straight lines, the intersection of which defines a temperature which is essentially the same

Figure 1 (left). High temperature oven and electrodes

Figure 2. Variation of dielectric strength and resistivity of high tension porcelain with temperature

as that defined by the two lines for the resistivity data. This is also true for fused silica, data for which are given in Figure 6. The dielectric strength data were taken from Moon and Norcross.[2] The transition is, of course, never sharp for either dielectric strength or resistivity, but quite gradual, as would be expected from the simultaneous operation of both the high and the low temperature mechanisms. Moon and Norcross[2] have proposed three separate regions of breakdown for glass, but it appears that their intermediate region is merely the transition region between the disruptive and the thermal regions. The available data for fused quartz given in Figure 6 appear to be insufficient to define the slopes of the two lines very well. Since fused quartz is an amorphous material, its dielectric strength at low temperatures would be expected to be less influenced by temperature than Figure 6 indicates.

Figure 7 shows that the power factor as measured at 100 kc also can be represented approximately by two straight lines when the logarithm of the power factor is plotted against the reciprocal of the absolute temperature. Some of the power factor data were taken from a previous paper,[4] which contains power factor and resistivity data for a number of ceramic materials. The dashed vertical lines indicate the transition temperatures as determined by the resistivity data. The transition temperatures as determined by the power factor data do not agree exactly with those determined by the resistivity data, but this is to be expected since the power factor and resistivity measurements were made on different sets of samples whose composition may vary slightly.

Attention is called to two anomalies in the power factor behavior. The first involves the smaller slope of the power factor curve for zircon porcelain in the high temperature region than in the low temperature region. The reverse is seen to be true for all of the other bodies whose power factors are given in Figure 7. This abnormal behavior has been observed in three different zircon porcelain compositions and so far there has been no clue as to what characteristics of zircon are responsible for the anomaly.

The second anomaly concerns the very sharp power factor peaks observed in alumina after subjection to d-c voltages at high temperatures. Figure 8 shows the results obtained on a 1/8-inch thick sample of alumina after subjecting it to about 500 degrees centigrade and a d-c voltage of approximately 500 volts for 30 minutes. It will be observed that the peaks are quite sharp and become sharper with increasing frequency rather than shifting to a higher temperature as in the case of the usual type of polarization. There was no significant variation in dielectric constant in the temperature range from 20 to 100 degrees centigrade. It appears that the temperature, the magnitude of the voltage and the time of its application are all important factors in producing this phenomenon. A slight change in these conditions may change the magnitude of the peaks and the temperature at which they occur.

Under more severe conditions of electrolysis, the peaks do not appear at all. For example, when a sample was subjected to 1,000 degrees centigrade and 3,000 volts direct current for nine hours, no peaks were observed in the temperature range from 25 to 70 degrees centigrade.

This treatment, however, resulted in a more than ten-fold increase in power factor and an increase from about 9 to 13 in dielectric constant over the same temperature range. Moreover, the sample showed a strongly negative temperature coefficient of dielectric constant up to 70 degrees centigrade, whereas the untreated sample showed substantially no change in dielectric constant in the same temperature range. Much more work is required to ascertain the conditions and the mechanism by which such a peculiar type of polarization is produced.

Discussion of Results

For convenience of discussion, the transition temperatures of the various materials considered in this paper are summarized in Table II. This tabulation shows the superiority of the special porcelains, fused quartz and mica over high tension porcelain for applications involving high temperatures. The transition temperatures, besides being of theoretical interest, should also be of practical value since they represent the temperature above which it is inadvisable to apply a sizeable fraction of the breakdown voltage if cumulative heating and subsequent instability and finally breakdown is to be avoided.

Table II. Transition Temperature for Various Materials

Material	Transition Temperature, Degrees Centigrade
High tension porcelain	100
Zircon porcelain	220
Alumina porcelain	250
Fused silica	280
Muscovite mica	380

Perhaps the principal reason for the low transition temperature observed in high-tension porcelain is the relatively high alkali metal content as Table I shows. Warburg, as early as 1884, established that conduction in glass is electrolytic in nature[3] due largely to alkali metal ions, and that Faraday's laws of electrolysis were satisfied. Thus, potassium, and particularly sodium because it has a relatively small molecular volume, are probably responsible for most of the conductivity in all of the bodies. Zircon porcelain has a considerably higher transition temperature than high tension porcelain which can certainly be attributed partly to its low alkali metal content. Table I shows that the flux for this body is largely calcium oxide which does not contribute greatly to conductivity in glass. The still higher transition temperature observed for the alumina body can be attributed partly to its low alkali metal content, and partly to its relatively higher melting point as is evidenced by the fact that a considerably higher firing temperature is required for this body than for the other two bodies. Thus, it may be concluded that large additions of alkali metals are undesirable in ceramic bodies designed for use at high temperatures.

Referring again to Figures 2, 3 and 4, the following further deductions can be made from the plotted data:

1. The resistivity of high-tension porcelain is considerably lower over the whole temperature range than that for the other two bodies.
2. The dielectric strengths in the low temperature or disruptive region are not significantly different for the three bodies and differences appear mainly in the high temperature or thermal region.
3. The d-c dielectric strength for all three bodies appears to be slightly higher than the 60-cycle a-c peak dielectric strength.
4. The dielectric strength of the $^1/_8$-inch thick samples is somewhat higher than for the $^1/_4$-inch thick samples.

All of the bodies show a large decrease in resistivity with increase in temperature. It has been shown by Kraus and Darby[4] that ionization of the constituents of glass changes only slightly with temperature. If this be true for the ceramic bodies, the increased conductivity at the higher temperatures must be due to increased velocity of the ions. The velocity of the ions can increase only due to a corresponding decrease in the viscosity of the medium in which they are moving. Bryson[5] and also Littleton and Morey[7] have reported data on glass which show that the resistivity decreases with temperature in much the same way that viscosity of the glass does. This explains why the higher melting bodies, which should have higher viscosities, are expected to show a lower conductivity at a given temperature, other things such as the degree of ionic dissociation being the same.

The coincidence of transition temperatures between two regions of breakdown and two regions of conductivity naturally leads one to suspect that both transitions might be ascribed to the same cause. The possibility of a change in structure occurring in the various ceramics at the transition temperature was carefully investigated. X-ray spectrographic studies were made which revealed the crystalline constituents in the various bodies and these are listed in Table I. The literature revealed that the temperatures at which changes in structures occur in all of the crystalline components are much higher than the transition temperatures found in this work. The possibility of a second order transition or the like taking place in the glassy or amorphous phase was also investigated. Coefficient of expansion data for the various bodies were carefully obtained over a wide range of temperature. In no case was a change in slope of the expansion curve observed in the region around the transition temperatures. Thus, there appears to be little likelihood that the transition temperatures observed are due to a change in

structure of the ceramic. The existence of two or more distinct straight lines with different slopes for alkali halides when the logarithm of the conductivity is plotted against the reciprocal of the absolute temperature has been reported by a number of investigators.[8–12] Brennecke,[8] for example, has reported a change of slope in the resistivity data for KCl at about 230 degrees centigrade. He found that, below this temperature, the resistivity is a function of the time of voltage application and this indicated the presence of dielectric absorption, whereas above this temperature he found no measurable dielectric absorption. Phipps and Partridge,[10] working at higher temperatures than Brennecke, found a change in slope for KCl at about 445 degrees centigrade. This transition is not sharp but gradual. These investigators concluded that the conduction below the transition temperature is due almost entirely to the positive alkali metal ions and above this temperature is due to both positive and negative ions. Thus, it is indicated that some alkali halides can show two transition temperatures, each due to a different cause. No indication of two transition temperatures was found, however, in any of the ceramic bodies investigated.

It appears difficult to find data on both dielectric strength and conductivity for alkali halides over a sufficiently wide range of temperature to include the lower transition temperatures. Von Hippel and Maurer[1] give breakdown data on KBr over a range of temperature extending from −160 degrees centigrade to 190 degrees centigrade. When these data are plotted on a logarithm versus $1/T$ plot, a transition temperature of about 75 degrees centigrade is obtained. Brennecke[8] gives resistivity data on several samples of KBr, one of which appears to have a transition temperature at about 70 degrees centigrade which is reasonably close to that determined by dielectric strength. The data, however, are so meager and the agreement among various investigators is so poor that further work should be done to confirm this. Of the two transition temperatures sometimes observed in conductivity data on alkali halides, it appears that it is the one occurring at the lower temperatures which should correspond to one determined by the dielectric strength data. The only thing that can be said at the present time is that Brennecke[8] has presented some evidence that this lower transition temperature is in the neighborhood of the temperature above which the conductivity becomes independent of time of voltage application.

In order to determine to what extent the resistance varies with time in the neighborhood of the transition temperatures on the ceramic bodies, the data of Figure 9 were obtained. For high-tension porcelain and alumina porcelain, it will be observed that below the transition temperatures (Table II), the resistance increases with time, while above the transition temperature the resistance is constant with time. Zircon porcelain behaves differently. Figure 9 shows the resistance increasing at even 76 degrees centigrade above the transition temperature. This peculiar behavior of zircon porcelain in contrast to that of other ceramics was also observed by Frey and Jesatko.[13] The exact reason for this difference in behavior was not established but the increase in resistance with time above the transition temperature could be due to electrolytic polarization brought about by the gradual drifting of the positive alkali and other metal ions away from the anode. Why this does not occur in all bodies is not known.

The effect of voltage on the resistance was also investigated. For voltages of the order of 100 to 500 volts, which are much below the breakdown voltages, the resistance was found to be independent of voltage below the transition temperature. Above the transition temperature, all bodies except alumina were found to have a resistance independent of voltage. Why alumina is an exception is not yet known. Ohm's law was also found to hold for alkali halides[8] over a temperature range from 20 to 450 degrees centigrade.

As mentioned previously, Phipps and Leslie[12] have found that both ions in

sodium chloride carry current above 500 degrees centigrade and below this temperature all of the current is carried by the positive sodium ion. This change from uni-ionic conduction to bi-ionic conduction occurs near the higher transition temperature, 450 degrees centigrade, that Phipps and Partridge[10] reported. Some evidence of bi-ionic conduction was also found for alumina porcelain at 1,000 degrees centigrade. The photomicrograph in Figure 10 shows cross-sectional views of the area directly under the electrodes of two 1/4-inch thick disks. The lower portion of the photomicrograph shows the disk after a d-c voltage of 3,000 volts had been applied for nine hours while the temperature was held at 1,000 degrees centigrade. Definite evidence of ion migration at both electrodes is apparent by the color change which extends partly through the disk from each face. The upper portion of Figure 10 shows the second disk after it was subjected to an a-c voltage of the same magnitude under otherwise similar conditions. No evidence of ion migration or color change is apparent with alternating current as is to be expected.

While bi-ionic conduction could explain the steeper slopes of the resistivity curves above the transition temperature, we have no evidence that it exists except at much higher temperatures. Since conduction due to the negative ion, just as is the case for the positive ion, decreases with decrease in temperature according to the law relating conductivity, σ with absolute temperature T, $\sigma = \sigma_0 e^{-1/T}$, only about one millionth of the conduction due to the negative ion is expected at the 250 degree centigrade transition temperature for the alumina porcelain compared with that which takes place at 1,000 degrees centigrade where evidence of bi-ionic was observed. Thus, the difficulty of establishing the temperature at which bi-ionic conduction is initiated can be appreciated.

The high power factor peaks for alumina porcelain shown in Figure 8 were considered in the light of a new polarization phenomenon in alkali halide crystals which was reported recently by Breckenridge.[14] This type of polarization is ascribed to the jumping of positive ions into vacant lattice sites. It appears possible that something similar could occur in alumina porcelain, but the evidence is against it because the experimental data are so different in the two cases. In the case of the alkali halides, the power factor and dielectric constant variations with both frequency and temperature are similar to those for the more usual types of dielectric polarization, whereas this is not true for the alumina porcelain body as has already been pointed out. All that can be said now regarding this peculiar behavior of alumina porcelain is that it must be related to a permanent displacement of charge which takes place at about 500 degrees centigrade upon application of d-c voltage. This phenomenon was not observed in any of the other bodies which were electrolyzed in a similar manner. It is possible, however, that the proper conditions for producing it in the other bodies were not found.

Passing now to dielectric breakdown, the actual breakdown is now generally believed to involve the release of an avalanche of electrons irrespective of whether it takes place in the disruptive or thermal region. There is plenty of evidence for this, since the final surge of current always takes place in so short a time that numerous attempts to obtain a complete record with high-speed oscillographs have failed. If ions alone were involved, the final process would be much slower. The disruptive and thermal regions differ only in the process by which the final stage is reached. In the disruptive region, the ions play an insignificant role, but in the thermal region the relatively large ionic conduction and the resulting heating effect promotes breakdown at a lower value than otherwise would be the case.

The recent theories on electric breakdown in solids all involve electronic processes. The most important ones are those proposed by von Hippel[17] and Frohlich.[18–21] The two theories are somewhat similar and differ only in the details. They both involve the formation of electron avalanches in the final stages which are produced by a restricted ionization-by-collision phenomenon somewhat analogous to that which occurs in gases. As the electrons gain velocity from the applied field, they are retarded by the

A.P.—alumina porcelain; Z.P.—zircon porcelain; H.T.P.—high tension porcelain

frictional effect of losing part of their energy to excite lattice vibrations. Breakdown takes place when the ionization becomes cumulative in spite of the frictional force. The positive space charge left by the displacement of electrons also plays an important role by distorting the field and weakening the material, thus resulting in cracks which have often been observed.[15–17]

Both theories have been found to be in qualitative agreement with experiment.[1,2] The details of the two theories will not be discussed, especially since there appears to be insufficient evidence to make a choice between them. Frohlich[21] has recently shown that the earlier theory of dielectric breakdown becomes invalid above a certain critical temperature T^1. This temperature is defined as the temperature at which the number of electrons in the conduction bands of the crystal has increased to the point where collisions of an electron with other electrons become more frequent than collisions of an electron with the lattice vibrations. Therefore, above T^1 a change in transfer of the energy which the electrons receive from the applied field should take place. The theory is too complicated to discuss in detail here, but it may be of interest to consider briefly the following simple relation which was derived by Frohlich:

$$\log F = K_1 + K_2/T$$

where F is the intrinsic dielectric strength, T is the absolute temperature, and K_1 and K_2 are constants involving the energy of electrons and the energy of the conduction bands. This relation states that the logarithm of the dielectric strength should decrease as the reciprocal of the absolute temperature. The relation applies only above the critical temperature T^1, and Frohlich cites the experimental data of von Hippel and Maurer[1] on soda lime glass and that of Thomas and Griffith[22] on varnishes as being in general agreement with the theory. The data for the ceramic bodies given in this paper are also in qualitative agreement with the theory. The transition temperatures repeatedly referred to in this work appear to be identical with Frohlich's critical temperature T^1 which he defines entirely in terms of an electronic mechanism. The fact that T^1 or the transition temperature has the same value for conduction as for breakdown should be of importance in the further development of breakdown theories. Some modification of the theory already appears to be necessary to take into account ionic conduction, which usually accounts for nearly all of the current flow in insulators up to, but not including, the final stage of breakdown. It certainly would be desirable to have data showing what proportion of total current is electronic at field strengths near the breakdown values. While much of the experimental data appears to be in qualitative agreement with the theory, further refinement appears necessary before quantitative agreement can be realized.

Summary and Conclusions

A study has been made of the electrical properties of a number of ceramics over a wide range of temperature. The superiority of several special porcelains over high-tension porcelain has been demonstrated for high-temperature applications. An interesting correlation was discovered between conductivity and electric breakdown behavior which should help throw some light on electric breakdown phenomena. The results are discussed in the light of existing theories of conduction and electric breakdown. Attention is directed to a number of unsolved problems with the hope that others will be stimulated into giving some thought to them. The more important conclusions which may be drawn from this work are as follows:

1. Special porcelains can be made whose major constituents are zircon and alumina, which have considerable advantage over high-tension porcelain, both electrically and mechanically, for applications involving high temperature.

Figure 10. Cross-section of alumina porcelain after subjection to 1,000 degrees centigrade and 3,000 volts

Top—a-c voltage; bottom—d-c voltage

2. When the logarithm of dielectric strength is plotted against the reciprocal of absolute temperature, the data define two straight lines of different slopes. The intersection of the two lines define a temperature which is called the transition temperature separating the disruptive and thermal regions of electric breakdown.

3. The transition temperature for high-tension porcelain is 100 degrees centigrade, that for zircon porcelain is 220 degrees centigrade, and that for alumina porcelain is 250 degrees centigrade. Mica and fused silica, in comparison, have transition temperatures of 380 degrees centigrade and 280 degrees centigrade, respectively.

4. It has been found that the transition temperatures for the dielectric strength data coincide with those for the resistivity data. This indicates that the underlying mechanisms in breakdown and conduction may be similar and this should help in throwing further light on electric breakdown in solids.

5. The transition temperatures for the ceramic bodies separate a region where the conductivity is dominated by dielectric absorption from that where the conductivity is largely due to electrolytic conduction. Zircon porcelain, however, appears to be an exception to this.

6. The experimental data on dielectric strength are in qualitative agreement with recent electric breakdown theories. Frohlich's critical temperatures, which separate the low and the high temperature regions of electric breakdown, appear to be identical with the transition temperatures determined by the resistivity and the dielectric strength data reported herein. Even though no quantitative agreement between theory and the practical data of this investigation is expected, some refinement of the theory appears necessary to account for the effects of ionic conduction.

Discussion

E. J. Murphy (Bell Telephone Laboratories, Inc., Murray Hill, N. J.): There are at least two ways of interpreting the relationship between breakdown strength and resistivity which has been demonstrated by Lindsay and Berberich: (a) by an electronic process recently proposed by Fröhlich, and (b) by an electrolytic process. The theory of breakdown by electrons as proposed by Fröhlich yields in a natural way a breakdown strength which increases with increasing temperature. But experimental evidence has shown that above a certain temperature, depending on the material, the breakdown strength decreases with increasing temperature. Fröhlich has attempted to explain this by the intervention of electron-electron collisions, before breakdown occurs. This is certainly the more interesting way of explaining the relationship found by Lindsay and Berberich.

However, I have for several years held the following view of how conductivity effects breakdown in solids. For very low conductivities there should be no effect. But for higher conductivities, such as ceramics and other dielectrics attain at higher temperatures, there is an indirect effect due to electrolysis. The products of electrolysis create regions of higher resistance in some dielectrics near one or both of the electrodes. As a consequence the voltage gradient becomes nonuniform; there is a higher gradient in the high resistance region than in the rest of the dielectric. Breakdown occurs first in this layer by the electronic process described in the theories of von Hippel and Frohlich. This change of potential distribution occurs the more quickly the higher the conductivity. The value of conductivity at which an observable reduction in breakdown strength due to this cause first appears depends upon the chemical compoaition of the dielectric and of the electrodes. Several peculiarities of behavior are described in the paper, such as unusual characteristics of the power factor–temperature curves. These are not inconsistent with the process depending on high resistance layer formation by electrolysis, though they do not require this explanation. Both the electronic and the electrolytic effects should occur in some degree. It is a question as to which predominates in determining the breakdown behavior in a given material. The experiments of Lindsay and Berberich are valuable steps in the direction of understanding the factors involved in the breakdown of ceramics at high temperatures.

H. A. Frey (Locke Insulator Corporation, Baltimore, Md.): The Lindsay and Berberich paper presents some very interesting data on a subject about which all too little is known at present. Many of the characteristics reported by Lindsay and Berberich check in a general way our experience in this field, some of which has been reported in a previous paper.[1] There are, however, several points of difference between our respective data.

In the first place Lindsay and Berberich did not find any variation in the resistivity of the materials with varying voltage gradient. In our investigation we have found that most of the materials showed a reduction in apparent resistivity with increasing voltage gradient. It is quite possible that this difference between the two sets of data is occasioned by the voltage ranges over which the investigations extended. In the Lindsay and Berberich investigation, resistivity was measured over the ranges of 100 to 500 volts, and on specimens 0.125 and 0.25 inch thick. The gradients were therefore of the order of from about 0.4 volt per mil to 4 volts per mil. In our data gradients of much greater magnitude were involved running up to about 70 volts per mil on high voltage porcelain. In our data there was considerable indication that at the extremely low-voltage gradients there was a tendency for the curve to flatten out which would account for the measurement of nearly ohmic resistance at the gradients used by Lindsay and Berberich.

The resistances measured by Lindsay and Berberich for high-voltage porcelain at the lower temperatures are considerably lower than those measured by us. At the higher temperatures there is a reasonably good check between the resistivities determined in the two investigations. At 60 degrees centigrade, however, our resistivity measurements are approximately ten times those of Lindsay and Berberich for high-voltage porcelain and for similar voltage gradients. We do not know how to account for this difference in measured resistivity. It is possible that the resistivities obtained by Lindsay and Berberich may have been influenced by surface leakage. I would like to ask the authors whether or not guard rings were employed on the test samples to eliminate the possible errors occasioned by surface leakage.

A third point of apparent disagreement lies in the ultimate breakdown strengths. At high temperatures the Lindsay and Berberich paper shows breakdown strengths for high-voltage porcelain several times that indicated by our data. At low temperatures the reverse is true, our data indicating dielectric strengths higher than that measured by Lindsay and Berberich.

I am unable to explain the disagreement at low temperatures. At high temperatures, however, I believe that the disagreement is largely one of method of measurement. Lindsay and Berberich have pointed out that their measurements were made using the American Society for Testing Materials one minute step-by-step testing procedure. At the higher temperatures, the time required for breakdown to occur from the beginning of the thermal drift period may be quite long. In our data we have made some measurements where the time interval at a constant voltage, prior to breakdown, has been as much as 112 minutes. We also know of some practical field experiments where the time required to breakdown has been as much as $4^1/_2$ hours. Obviously with a one minute step-by-step test, these slow drifting failures would not be detected so that the measured breakdown strengths would be substantially higher. We believe that this probably accounts for the difference in breakdown strengths between our data and the Lindsay and Berberich data. We therefore feel that the data obtained by one minute step-by-step method must be used with caution in practical designs involving high temperature applications.

The theoretical discussion advanced by the authors is quite interesting and may well stimulate further work in this field.

REFERENCE

1. THE ELECTRICAL PERFORMANCE OF CERAMIC DIELECTRICS AT ELEVATED TEMPERATURES, H. A. Frey, J. M. Jesatko. AIEE TRANSACTIONS, volume 5, 1496, pages 911–9.

E. W. Lindsay and L. J. Berberich: We wish to thank Murphy and Frey for their informative and illuminating discussions. The information contained in them should make valuable additions to the paper. A number of questions were raised in both of these discussions which appear to require further comment.

Referring first to Murphy's remarks, we think the suggestion that electrolytic phenomena play an important role in high temperature breakdown appears to be quite plausible when d-c voltages alone are considered. As a matter of fact, considerable evidence of electrolysis and ion migration is shown in the lower part of Figure 10 of the paper in the form of discolorations produced upon application of a d-c voltage on the ceramic body at elevated temperatures. With a-c voltages, however, no evidence of electrolysis was found, although it may have taken place to such a slight extent that it remained undetected. In any case, with a-c voltages, the suggestion that electrolytic phenomena play a role loses some of its appeal. If electrolysis played a dominating role, then one would expect appreciably lower values of dielectric strength with direct current than with alternate current. The data in the paper, however, show that d-c and a-c peak values of dielectric strength are not greatly different. Thus, it appears that factors other than electrolysis enter into the breakdown mechanism.

Referring now to Frey's comments, most of the differences observed in his and our results can be ascribed to differences in methods of test used. He is correct in ascribing the lack of variation of resistivity with voltage to the low voltage gradients used in measuring resistivity. We also found deviations from Ohm's law in all of the bodies investigated at higher gradients. It is customary, however, to measure resistivity at gradients less than 10 volts per mil in order to avoid any temperature rise within the material due to I^2R heating. Frey purposely used much higher gradients in his measurements, and lower values of resistivity at the higher gradients are to be expected.

Frey points out that our resistivity values for high-tension porcelain in the low temperature region are lower than values obtained in his laboratory. This could be due largely to differences in composition of the samples and to a lesser extent to surface leakage. It is true that we did not use guard rings because they would have unduly complicated our apparatus which was designed to go over a much wider temperature range than that covered by Frey. Surface leakage may have been a factor at room temperatures during periods of high humidity, but as the temperature is raised, the humidity is reduced so rapidly that we would expect very little effect due to this cause at temperatures even as low as 60 degrees centigrade at the low voltage gradients that were used.

Resistivity variations of the order 10 to 1 are not uncommon among samples from several batches of supposedly the same composition. Therefore, it is not at all improbable that most of the differences referred to by Frey could have been due to slight compositional variations. Furthermore, since resistivity values are influenced by so many variables, several of which have just been mentioned, no high accuracy as to absolute values are to be expected. We do wish to emphasize, however, that considerable significance can be attached to the relative values in the three types of bodies investigated in this work, for the same procedure was used in all cases.

The differences in breakdown strengths to which Frey refers can be ascribed very likely to the differences in methods of test used in the two laboratories. This is particularly true at high temperature as he has already explained. We would expect lower values in the type of test he used where the voltages are applied for a much longer time than is the case in the ASTM one minute step test. It is questionable, however, whether the method of test used by Frey has much more practical significance than the one we used. In his tests, the voltage at which thermal instability arises is determined, among other things, by the dimensions and the rate at which heat can be dissipated from the sample. Therefore, test results on disk samples might be quite different from those on an insulator used in practice having entirely different dimensions and heat dissipating properties. Both types of tests have their merits and we agree that Frey's type of test may have greater practical implications. Again we wish to emphasize that too much significance should not be attached to the absolute value of the breakdown strength, for such values can be influenced by many factors. The relative values, however, are significant and show without question the superiority of the zircon and alumina porcelains over high tension porcelains for high temperature applications. We believe also that the maximum temperature at which a given voltage can be safely applied to a ceramic insulator is closely related to the transition temperature for that body.

In closing, we wish to call attention to several difficulties that we have had with nomenclature. The first has to do with the name of the most commonly used porcelain in the electrical industry, namely, "high tension" or "high voltage" porcelain. This name might indicate that this type of ceramic is better for high voltage applications than the other bodies described. The paper shows, of course, that this is not true, for the other bodies will withstand even higher voltages, particularly at the higher temperatures. The name "high-tension porcelain" may therefore cause some confusion. To avoid this confusion, the name "silica porcelain" could be assigned to this ceramic since it contains a major proportion of silica as Table I of the paper shows. This also would be more consistent with the names assigned to the other two ceramics investigated. In view of the growing importance of the other ceramics, we believe some consideration should be given to the name suggested to avoid confusion in the future.

The second difficulty has to do with the so-called "thermal region of breakdown". Frohlich has suggested to us, in a private communication, that the word "thermal" should be avoided in referring to the region of breakdown where the breakdown strength decreases with increasing temperature. We heartily agree with him and the only reason we used the term at all is because of the lack of a better term and also because the term has been used for many years, particularly since K. W. Wagner developed his thermal theory in 1922. As Frohlich points out, there is now considerable evidence that the decrease of breakdown strength with increasing temperature may take place without a rise in temperature over the surroundings of any part of the sample under test. The decrease in breakdown strength with increase in temperature, as both Frohlich and von Hippel have shown, can be accounted for by purely electronic considerations, which involve no I^2R heating in the sense that Wagner has treated the problem. This does not mean that a thermal rise is absent when breakdown strength decreases with increasing temperature, but that it may be absent. Therefore, to avoid confusion, perhaps the term "high temperature region of breakdown" should be substituted for the term "thermal region of breakdown" when reference is made to the region above the transition temperature. For the region below the transition temperature, the term "low temperature region of breakdown" is suggested. Some better terminology is obviously desirable and perhaps someone can invent a more satisfactory one than we have suggested.

A New Reactance Distance Relay

C. G. DEWEY
MEMBER AIEE

J. R. McGLYNN
APPLICATION PENDING

THE high level of industrial and commercial activity has created a demand for electric power greater today than at the peak of wartime production. Installation of additional generating capacity and new transmission lines has been unable to keep up with this growth in power demand. This has led to transfer of additional power over existing lines, thus making continuity of service more vital than ever.

Protective relay characteristics necessary to maintain the greatest continuity of service are high speed clearing of faults, selectivity to avoid false tripping, and insensitivity to power swings.

Over the past 15 years distance relays operating on reactance or impedance have been most widely used in providing this type of protection. When these were supplemented with carrier pilot channels, high-speed tripping was obtained for faults anywhere in the protected section.

The transfer of additional power over existing lines has caused a corresponding increase in the number and severity of power swings, particularly on the longer lines. To cope with this problem greater phase angle discrimination was required in a distance relay. For this reason the mho relay[1] was designed in which this characteristic is inherent. For over two years mho relays have been used for protection of long or heavily loaded lines[2] because they are less liable to tripping on power swings than the conventional reactance or impedance relays. However, there are two limitations to the application of mho relays on short lines.

1. The mho units are not accurate if the fault voltage is less than about eight volts, phase to phase, at the balance point usually two to three secondary ohms minimum.

2. On short lines arc resistance increases the impedance so that the fault may appear to be in the next zone.

Because of these limitations, reactance relays have been applied to short lines.

While the problem of power swings is more common in the protection of long lines, it may also be a serious factor on short lines under certain circumstances. For instance, the short line section may lie between two longer sections so that it contains the electrical center of the system. Under these conditions the starting unit of the present reactance relay is susceptible to operation because it does not have the same reach on phase-to-phase faults as on balanced conditions. To eliminate this difference a new distance relay has been developed for the protection of short lines.

This new relay retains the ohm unit of the present reactance relay which, due to its high accuracy, plus and minus 2 per cent, can be set for first zone tripping up to 90 per cent of the protected section. However, the single-current 2-voltage starting unit has been replaced by a mho starting unit.[3] To obtain the desired characteristics, this unit is energized by the proper quantities, phase-to-phase voltage and the 2-phase currents. These are the fault voltage and the currents in the faulted phases on a phase-to-phase fault.

Description of Relay

In developing this new reactance relay, it seemed logical to follow the pattern of the mho relay, that is, the combination of three single-phase distance relays and a separate timing relay per 3-phase terminal. The following paragraphs give a brief description of the operation of the new terminal.

Paper 48-178, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28–30, 1948. Manuscript submitted February 13, 1948; made available for printing March 12, 1948.

C. G. Dewey and J. R. McGlynn are both with the General Electric Company, Philadelphia, Pa.

Under normal conditions the ohm unit may be open or closed depending upon the reactive component of the load impedance. The mho unit will be open because it is provided with voltage restraint.

On a fault in the nontripping direction, the mho unit will remain open because of its directional properties.

If a fault occurs in the protected section within the reach of the ohm unit setting, the ohm unit closes instantly, and may even be already closed, and the mho unit operates to set up the trip circuit immediately. The mho unit is provided with memory action so that faults near the bus may be cleared quickly and positively.

When a fault occurs beyond the first zone setting of the ohm unit, its contacts will be open so that tripping cannot occur when the mho unit closes. In this case the mho unit energizes the timing relay. After a predetermined time the reach of the ohm unit is extended to the second zone through the operation of its auxiliary element. If this change in reach is sufficient to allow the ohm unit to operate, tripping will now occur. When the fault is beyond this ohmic reach, the timing relay continues to operate for an additional preset time after which tripping occurs independent of the ohm unit operation. Should the fault be cleared at any time during this period, the mho unit contacts open and the timing relay resets.

Ohm Unit

The ohm unit is shown schematically in Figure 1. The four laminated poles surround the inner core with a small annular air gap between. A hollow aluminum cylindrical rotor, secured to the shaft carrying the moving contact, turns in this gap. The contacts, protected from excessive forces by a friction clutch, are held in the open position by a light spiral spring which also serves as a lead-in for the contact current.

This induction cylinder unit produces a

Figure 1. Schematic diagram of the ohm unit connected between phases 1 and 2

substantially constant torque at all points in the cycle. Also its torque is dependent on rate of change of current, rather than magnitude, thus making it relatively insensitive to offset currents. Because of these two factors, high-speed operation can be obtained without danger of excessive overreach.

The principle of operation of the reactance ohm unit can be explained most simply by considering first a single-phase system and then showing how the same principle may be applied to a 3-phase system. In Figure 2 is shown a single-phase system in which it will be assumed that a reactance unit is desired at A which will close its contacts for all faults between conductors occurring to the left of P, for example at F.

For simplicity it will be assumed that there is no impedance in the fault. It can be seen at once that

$$E/I = Z_{AF} \tag{1}$$

where E and I are defined from Figure 2 and Z_{AF} is the impedance of the loop, AF.

Operation is then required when

$$E/I < Z_{AP} \tag{2}$$

where Z_{AP} is the impedance of the loop, AP, or, since the reactance principle is to be used, when

$$E \sin \theta / I < X_{AP} \tag{3}$$

where θ is the angle by which the current lags the voltage.

A unit is then required which will be just ready to operate when

$$E \sin \theta / I = X_{AP} \tag{4}$$

and so constructed that a decrease of the ratio E/I will cause operation. Such a unit is indicated schematically in Figure 3.

This figure represents the operating element of the induction cylinder unit.

Figure 2. Simplified single-phase transmission line

As in an induction motor, it is necessary to have a difference in time phase of the magnetic flux in alternate poles in order to produce a torque on the rotor. The front and back poles are called polarizing poles.

The flux in the right-hand or current pole is made to lag its current about 90 degrees so that in conjunction with the polarizing poles it produces clockwise torque

$$T_I = K_1 I^2 \tag{5}$$

where K_1 is a proportionality constant.

The left-hand or potential pole has its coil tuned to phase resonance[4] so that its current is in phase with E, thus it works with the polarizing poles to produce a torque

$$T_E = K_2 EI \sin \theta \tag{6}$$

where K_2 is a second constant. When $\sin \theta$ is positive this torque is counterclockwise to oppose the current torque.

If then

$$K_1 I^2 = K_2 EI \sin \theta \tag{7}$$

no net operating torque will be produced. Also, a decrease in the ratio E/I will cause a net clockwise torque.

From equation 7

$$K_1/K_2 = E \sin \theta / I \tag{8}$$

If then the constants are so chosen that

$$K_1/K_2 = X_{AP} \tag{9}$$

the net torque is zero when a fault occurs at P in Figure 2. Thus a unit has been described which fulfills the requirements set forth for the single-phase system.

It has been well known since 1931 that for a 3-phase system, a unit operating on delta current and voltage will operate in the same manner for all types of interphase faults at a given location.[5] While the delta voltage can be obtained readily in most cases, quite often the delta current is not available without using auxiliary current transformers. However, it is possible to obtain the same effect in the relay by means of two concentric coils, each carrying one of the star currents.

By this means the principles described for the single-phase system are made applicable to a 3-phase system. It should be noted that the reactance measurement is phase-to-phase or twice the phase-to-neutral reactance which is used for convenience in application ratings.

The ohm unit as actually used differs slightly from the foregoing description in that each of the two polarizing coils indicated in Figure 3 is replaced by two coils, one on each side of the pole as shown

Figure 3. Schematic diagram of a single-phase ohm unit

in Figure 1. Also, adjustable resistors are connected in parallel with the capacitors. These resistors provide the required factory adjustments for the unit and also help to damp out undesirable transients which may be present when a fault occurs.

Control of the ohm unit reach is afforded by means of a tapped autotransformer in the potential circuit. Reducing the tap setting reduces K_2 in equation 9, thus increasing the reach.

At low currents the ohm unit reach is reduced because of the torque required to overcome friction and the lead in spiral. A typical accuracy curve under phase-to-phase fault conditions is shown in Figure 4. For 3-phase fault conditions the curve is displaced to the right because the two currents are not in phase.

Mho Starting Unit

The mechanical construction of the mho unit is similar to that of the ohm unit except that it is provided with two circuit-closing contacts. As indicated in Figure 5, this unit is also energized by phase-to-phase voltage and the two phase currents. The mho unit has been described previously,[1] so its characteristics will be set forth only briefly here.

The side poles are energized by potential to produce the polarizing flux. The front pole is energized by current to produce a directional torque dependent on the phase angle between this current and the polarizing voltage. Control of the maximum torque angle is afforded by an adjustable resistor in the phase shifting circuit.

The back pole is energized by potential

Figure 4. Variation of ohm unit reach with current magnitude for phase-to-phase faults

Figure 5. Schematic diagram of the mho starting unit connected between phases 1 and 2

from an autotransformer to produce a voltage restraint torque. The tap setting of this autotransformer determines the amount of voltage restraint, and hence the *EI* torque required to overcome this restraint. The reach of the unit is thus controlled by a simple field adjustment.

Timing Unit

The timing unit is provided in a separate relay. The operating magnet is a curved solenoid called a Rotonoid, having an armature which rotates through 180 degrees.

This Rotonoid, shown in Figure 6, winds up a spiral spring to drive the main shaft which carries a circular calibrated scale and two adjustable insulated cams for operating the contacts. Connected to this main shaft through a set of spur gears is a magnetic damping element for regulating the speed of operation. This element, shown in Figure 7, consists of a copper cylinder rotating in an annular air gap across which exists a permanent magnet field. The relative position of the cylinder in the air gap determines the amount of damping obtained. To insure good alignment all the parts are mounted on two similar parallel plates, following the pattern of good watch and clock design. Reliability is assured with this design which, employing high torque on the damping element and only one set of gears, is subject to a minimum amount of friction.

Additional Elements

In addition to the basic units described, auxiliary elements are provided to insure co-ordinated operation of the relay terminal. Since the mho starting unit is polarized by the fault voltage, it resets somewhat slowly when a second or third zone fault is cleared elsewhere. To insure against inadvertent tripping during this resetting interval, the first zone trip circuit is opened about 0.03 second after the mho unit operates. As this might prevent first zone tripping on faults near the end of the ohm unit reach, an auxiliary element restores the trip circuit if the mho unit remains closed for 0.015 second after the ohm unit closes. The one cycle delay which this may cause in clearing first zone faults has relatively little effect on the over-all protection since it is added only for faults in about the last 10 per cent of the zone on which the ohm unit is relatively slow.

A target is provided in each distance relay to show which phases are affected, while targets in the timing relay indicate in which distance zone tripping occurs. A seal-in element is provided in the timing relay to protect all the trip circuit contacts.

Ratings and Settings

Three different ratings of ohm units are available for covering various lengths of lines. These are 0.25 to 2.5; 0.5 to 5; and 1 to 10 ohms phase to neutral. In selecting the rating for a particular application, the highest minimum ohms should be used which will permit the required first zone setting. This insures a high operating torque level since the first zone potential tap setting will always be 50 per cent or more with the 2:1 steps

Figure 6. The Rotonoid operating magnet of the new timing relay

Figure 7. The magnetic damping element of the new timing relay

of minimum ohmic ratings available. In each case the upper part of the ohmic range is intended only for relatively high second zone settings which may be desirable.

The same mho starting unit is used with all three ohm unit ratings and has a range of 2.5 to 20 ohms phase to neutral. The maximum torque angle may be varied over a range of 60 to 75 degrees lag by means of an adjustable resistor.

The reach of both units is adjusted by means of taps on an autotransformer in the potential circuit. With this arrangement, the first zone setting may be made in steps of no more than one per cent without any mechanical adjustment of the unit.

The two insulated cams operating the contacts of the timing relay can be adjusted individually. A range of time adjustment from 0.15 to 3.0 seconds is provided.

Testing

Since only one voltage is used in the operation of the new relay, a single-phase source is sufficient for making all tests. The test box and reactor now used for testing distance relays, provide the simplest and most accurate means of making settings. The reactor is used as the fault impedance in combination with a tapped resistor to simulate arc or line resistance in the test circuit. The use of this equipment obviates a phase shifter and meter accuracy since the reactor is used as a standard of comparison. This method of testing has the further advantage that it matches closely the transient conditions encountered during a fault.

Summary

The new reactance relay has the inherent high speed and accurate distance measurement characteristics of the present relay. In addition, it has the following advantages:

1. The mho starting unit reach is the same for all faults involving more than one phase.

2. The new timing relay provides more accurate and consistent timing. It has a radically new operating magnet and employs a powerful magnetic damping element both of which reduce the gearing to one set of gears.

3. Only a single phase supply is required for making tests.

Discussion

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): The redesign of the starting unit for the reactance-type distance relay to incorporate the mho circle characteristic should extend the application of reactance relays to short lines where power swing and load ability considerations are becoming more important. As pointed out by the authors, the old starting units used for reactance relays varied over a wide range in characteristics since they responded differently to phase-to-phase and 3-phase faults. This made it necessary to set the relay one and a half to two times as sensitive to 3-phase load current as should be necessary with the mho-type starting units.

It appears that no fundamental changes have been made in the design of the reactance or mho units used previously; but these units have been installed in one case, resulting in a reactance relay having improved starting unit characteristics. The timer used previously with the distance relays has been completely redesigned, and it would be helpful to know more concerning its connections and operation with the new type reactance relay. Reference is made to additional elements in the new timing relay which apparently are necessary to co-ordinate the timing between the mho and ohm units to prevent possible incorrect relay operation. It appears that this may result in additional contacts in the trip circuit, which is undesirable. One of the advantages of using mho-type element is its inherent directional characteristics making it unnecessary to have additional directional contacts in the trip circuit. However, if additional auxiliary relays must be added to the distance relay in order to achieve proper co-ordination of the mho unit with the ohm unit, the advantages of this simplicity are lost. It is especially undesirable to have relay back contacts in tripping circuits. It would be helpful if the authors could include a simplified schematic wiring diagram of the new reactance relay and its associated timer, showing the over-all tripping arrangement.

It is hoped that further developments will make it possible to co-ordinate the starting and ohm units to take full advantage of the simplicity in the tripping circuits and keep the number of contacts in the tripping circuit to a minimum.

The authors state that the seal-in elements are provided in the timing relay for all tripping circuit contacts. We understand that consideration has been given to changing this design and moving the seal-in elements back into the individual relay cases. It would be well if the authors could comment concerning this change and explain the advantages of this new arrangement. We understand that the new timer coils are intermittently rated, which we believe is undesirable, especially for installations where the relay potential supply is from line side potential devices that are subject to being de-energized for long periods of time. We prefer a timer having a continuous rating. It would be helpful if the authors would comment concerning this rating and point out why it would not be preferable to design a timer having a continuous rating.

Since the new relay is a single-phase unit, it should be possible to simplify the method of testing, which is desirable. The authors point out that test reactors may be used for setting the relay. One point that should be kept in mind when using the test reactor is not to exceed its current rating, since this may produce saturation. When the reactor saturates, poor wave form results in the test voltage and incorrect calibration of the relay may result.

Feeder Voltage Regulator Accuracy Standards

W. E. BIRCHARD
MEMBER AIEE

Synopsis: New standards* for the accuracy of feeder voltage regulator control devices will provide much needed performance specifications. A working knowledge of their provisions will be an important aid for distribution engineers.

Electrical distribution systems are usually designed and operated to maintain the consumers' voltage within specified limits. These limits are determined either by state commission rules or by utility engineering standards for good service. Variation in consumers' voltage results principally from three causes:

1. Regulator band width.
2. Regulator control errors.
3. Line drop (including transformer drop).

On a distribution system the difference between the maximum voltage of the first consumer and the minimum voltage of the last consumer, over a period of time, is the sum of items 1, 2, and 3 above. (The first consumer is the one electrically nearest the supply, and the last consumer is the one electrically farthest from the supply.) These maximum and minimum voltages must be within the specified limits mentioned before. Thus, if either the regulator band width or the regulator control errors are decreased it is permissible to increase the line drop in either of two ways, by increasing the load on the feeder, or by extending the length of the feeder. A third possible benefit is to maintain the same maximum voltage for the first consumer and increase the minimum voltage of the last consumer by the amount of decrease in band width or control errors and maintaining a higher average feeder voltage.

It is apparent that decreasing regulator control errors and decreasing band width are equally important, and that all three possible benefits of either or both have a real economic value.

Need for Accuracy Standards

Many factors such as variations in temperature, frequency, and load affect the accuracy of regulator control devices. The over-all error of the several control devices of an automatic feeder voltage regulator might be based on any of innumerable possible combinations of various ranges of these factors. Obviously, it is very important to both utilities and manufacturers to have a single set of standards universally accepted by both. The standards should list the sources of error to be included and specify procedures for determining the errors. They should also specify how the errors are to be combined in determining the over-all error and define accuracy classes. Ranges of variation of temperature, frequency, and so forth, recognized by any standards will necessarily be somewhat arbitrary, but if they have been chosen to cover the variations normally encountered in actual practice the advantages of having a single set of universally accepted standards will outweigh the disadvantages of not having specifications tailored exactly to the conditions encountered in a particular utility system. Without such standards, statements of regulator control accuracy have been cumbersome and extreme care has been required to avoid misunderstandings between manufacturers and utility engineers.

When the accuracy standards have become established, distribution engineers can readily select regulators having accuracies to suit their needs and design their systems to take full advantage of the accuracies selected. Generally, it will be found economical to obtain high accuracy regulators and use the lower cost line construction permitted by trading line drop for regulator control errors. If a distribution engineer has not known how accurate his regulators are he may have been over-conservative and allowed for more control error than necessary, thus requiring needlessly expensive line construction to keep his line drop low. Of course, he should not accept accuracy guarantees blindly, but should have a working knowledge of the accuracy standards so that he can determine whether his operating conditions fall within the ranges of variables recognized by the standards. Generally they will, but some exceptions may occur for which additional allowances should be made.

Proposed ASA Standards for Regulator Control

The proposed ASA standards for "Accuracy of Control Devices for Induction Voltage and Step Voltage Regulators," meet the requirements outlined before. They classify the errors into two groups:

1. Errors occurring in the potential supply and voltage regulating relay with its ballast.
2. Errors occurring in the current supply and line drop compensator.

Since the recognized sources of error are not the same for both groups, and the test procedures are different, the two groups will be discussed individually.

Potential Supply and Voltage Regulating Relay

Although errors occurring in the line drop compensator are determined sepa-

* Standards for "Accuracy of Control Devices for Induction Voltage and Step Voltage Regulators," have been prepared by a working group of the AIEE transformer subcommittee and recently submitted to American Standards Association (ASA) Sectional Committee C57 for inclusion in the American Standards for Transformers, Regulators, and Reactors.

Paper 48-177, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted February 16, 1948; made available for printing March 18, 1948.

W. E. Birchard is with the motor engineering division, General Electric Company, Pittsfield, Mass.

rately, portions of the compensator circuit are usually included as part of the voltage circuit even with the compensator set on zero. These compensator elements function as part of the voltage regulating relay ballast. Compensators for modern single-phase regulators are usually provided with phase-shift networks to obtain correct line drop compensation on 3-wire 3-phase systems without interconnecting the control circuits. Since the impedance characteristics of the compensator may be different for the various phase-shift connections, it is necessary to determine the errors occurring in the voltage regulating relay and its ballast for each of the phase-shift connections.

Test Conditions. The accuracy of the potential supply and voltage regulating relay with its ballast is determined under the following specified conditions:

1. Both the resistance and reactance elements of the compensator are set on zero.
2. The applied voltage is to have a constant wave form with a deviation factor not exceeding 0.03 as defined in ASA *C-42*, paragraphs 10.95.420.
3. For 3-phase regulators, the three phase voltages and the three line currents are to be balanced.
4. The band width of the voltage regulating relay is excluded in determining accuracies.

The potential supply is usually tested separately from the voltage regulating relay and its ballast, and then the errors are combined as explained under Summation of Errors.

Setting the compensator on zero eliminates all possibility of introducing compensation voltages which would be extraneous variables for this series of tests. The temperature and frequency characteristics of the voltage regulating relay and ballast circuit of modern regulators with which the writer is familiar are not affected by the setting of the compensator. For control circuits where this is not true more representative results would be obtained with mid-range compensator settings of resistance and reactance; however, this would require more elaborate test specifications to eliminate compensation voltages resulting from load current.

Condition (2), constant voltage wave form, is believed to be representative of most power systems. Condition (3), balanced voltage and current, is often not obtained in practice. However, the degree of unbalance is generally held to a minimum, and both test specifications and interpretation of results would be greatly complicated if various combinations of unbalance were included.

Exclusion of band width simplifies the Standards, but from the practical application viewpoint it should not be ignored. The band width of the modern voltage regulating relay and ballast combination with which the writer is familiar is practically independent of temperature and frequency variations over the ranges specified by the standards, but this is not an inherent property of all voltage regulating relays. If the band widens with temperature change the widest band encountered in the range of operating temperature should be recognized in designing a distribution system. Admittedly, effective band width is a controversial subject involving consideration of the duration of voltage fluctuations, but any such transient effects will be superposed on the steady state response of the voltage regulating relay.

It seems to the writer that for testing the potential supply the standards should also either specify that the regulator supply voltage is to be held constant at rated value throughout the tests, or that the output voltage is to be held constant, at rated value, since these conditions may have some effect on potential winding errors. Both the supply and output voltages vary in actual service, but since line drop compensation is generally utilized it is believed that for any typical installation the regulator output voltage will vary more than the supply. Therefore, it is recommended that the supply voltage be held constant as a test condition.

Reference Values. The per cent error is based on the following reference conditions:

1. Regulator on its neutral position.
2. 120 volts in the potential control circuit.
3. Rated frequency.
4. Zero load current.
5. Ambient temperature plus 25 degrees centigrade.

Sources of Error. The recognized sources of error, in addition to characteristics of the devices, and the ranges to be considered are listed below.

1. Regulator position; maximum raise to maximum lower.
2. Load current; zero to rated current in the series winding at a power factor of 80 per cent lagging.
3. Ambient temperature; minus 30 degrees centigrade to plus 40 degrees centigrade.
4. Frequency; plus and minus 0.25 per cent.

The only effect of the first two sources of error on the voltage regulating relay and its ballast is that of load current in raising the ambient temperature of the control devices above the ambient of the air surrounding the regulator. For regulators equipped with potential transformers the temperature effect of load current is the only result of error sources (1) and (2) which affects accuracy of the potential supply. For regulators having built-in potential supply windings, in general, the effective voltage ratio between the main windings and the potential supply windings is affected by regulator position and by both the magnitude and power factor of the load current. The power factor is defined as "the load power factor of the circuit at the output terminals of the regulator," and for single-phase regulators this involves testing at three power factors. On single-phase and 3-phase 4-wire systems the power factor for the regulator is the same as for the system; the load current lags the output voltage by 36.87 degrees. However, on 3-phase 3-wire systems the power factor for a single-phase regulator is greater or less than that of the system depending upon phase rotation and the way the regulator is connected into the circuit; the load current lags the output voltage by 6.87 degrees or by 66.87 degrees.

The ambient temperature is specified as that of the air surrounding the regulator. Since the control devices are usually tested separately from the regulator, the temperature rise of the control cabinet above the ambient of the surrounding air must be determined at no load and with full load on the regulator. Then when testing the voltage regulating relay and its ballast the temperature rise of the cabinet at full load must be added to the upper end of the temperature test range, and the lower limit of the temperature test range should be adjusted by the cabinet rise at no load. The lower end of the range will generally be affected very little because at no load the cabinet temperature will be nearly the same as that of the surrounding air. For example, if at full load the temperature of the air inside the control cabinet is found to be 10 degrees centigrade above the ambient of the air surrounding the regulator, and at no load 2 degrees centigrade above the surrounding air, then the temperature range for testing the voltage regulating relay separately would be minus 28 degrees centigrade to plus 50 degrees centigrade instead of minus 30 degrees centigrade to plus 40 degrees centigrade. The effect of regulator load on the temperature of potential supply windings or transformers should be included in a similar manner. Calculated

temperature errors based on measured resistances and measured temperature rises above ambient should be satisfactory for potential supply windings and transformers.

Only a small variation in frequency is recognized. Plus and minus 0.25 per cent is plus and minus 0.15 cycle for a 60-cycle system. Probably the instantaneous frequency fluctuation on some small systems is greater than this, but presumably the larger systems hold within these limits. Frequency variation may cause an error in voltage regulating relay and ballast combinations, but not in potential supply windings or transformers.

It is, of course, not intended that the manufacturer shall make a complete set of accuracy tests on each regulator; such a procedure would increase the cost prohibitively. Therefore, the manufacturer must make due allowance for manufacturing variations in individual units.

Summation of Errors. Errors in the potential supply and voltage regulating relay are determined for each of the connections of the compensator phase shift network. The zero phase-shift connection is used on single-phase and 4-wire 3-phase systems; the errors determined for the voltage regulating relay and ballast for this connection should be combined with the errors in the potential supply for a load power factor angle of 36.87 degrees (0.80 power factor). The 30-degree phase shift connections are used on 3-wire 3-phase systems. The relay and ballast errors for the 30-degree leading phase shift connection should be combined with the potential supply errors for a regulator load power factor angle of 6.87 degrees. Likewise, the errors for the 30-degree lagging connection should be combined with those for a regulator load power factor angle of 66.87 degrees.

The standards define the "per cent plus error" of the potential supply and voltage regulating relay as "the sum of the plus errors" and likewise the "per cent minus error" as "the sum of the minus errors" due to variations in regulator position, load current, ambient temperature, and frequency as outlined under Sources of Error. This seems straightforward enough at first glance, but further consideration shows that definitions of "plus errors" and "minus errors" are needed for proper classification. For example, if a potential transformer or potential winding supplied a voltage of 120.5 when it should have been 120.0, the error would, in the absence of definition, probably be considered plus 0.5 volt. Likewise, if 120.5 volts were required to balance a voltage regulating relay when it should have balanced at 120.0 volts, the error would probably be considered plus 0.5 volts. Yet it is apparent that the combination of this particular potential supply and relay would hold correct regulator output voltage; in other words, these two errors cancel each other.

In order that consistent and practical results may be obtained in applying the accuracy standards the writer proposes the following definitions:

Errors causing the regulator to maintain a voltage level greater than the reference level are plus errors.

Errors causing the regulator to maintain a voltage level less than the reference level are minus errors.

If these definitions are accepted the error in the potential supply of the foregoing example would be "minus" because with it the regulator would maintain lower than nominal line voltage to supply 120.0 volts to the control circuit. The voltage regulating relay error would be "plus" because the regulator would have to hold higher than nominal line voltage to balance the relay. Combining these two errors results in zero net error which is in agreement with actual performance if the conditions producing them occur simultaneously. As indicated before, plus errors and minus errors are not combined in determining the over-all error, but proper classification is needed because plus errors are added together and likewise minus errors.

Current Supply and Line Drop Compensator

The accuracy of the current transformer, line drop compensator, and associated circuits is determined in terms of the voltage errors produced by these devices in the potential circuit. They are tested in combination.

Test Conditions. The accuracy of the current supply and line drop compensator is determined under the following conditions:

1. Frequency approximately rated.
2. Ambient temperature approximately plus 25 degrees centigrade.
3. Voltage regulating relay adjusted to balance at approximately 120 volts.
4. Compensator elements set on mid-range marks.

Conditions (1) and (2) are intended to indicate that frequency and temperature are to be held constant throughout a test. No attempt is made to evaluate frequency and temperature errors in the compensator. The recognized range of frequency variation is small and reactive line drop is proportional to frequency; even with phase-shift networks the discrepancies between reactance compensation and actual reactive line drop due to frequency variation will be very small. Any attempt to evaluate temperature errors in the compensator would be too involved to be practical. To supply perfect resistance compensation, the resistance element must have the same temperature coefficient as the lines and transformers which it represents and it must be subjected to the same temperatures, or have a combination of temperature and temperature coefficient which produces an equivalent result. Since lines and transformers vary over different temperature ranges, and are represented in different proportions of the compensator settings on various systems, it is hopeless to try to design a compensator with an equivalent effective temperature coefficient. Furthermore, some regulators are installed indoors and some outdoors, and even for outdoor regulators the control cabinets do not follow exactly the same temperature cycles as lines and distribution transformer windings. Fortunately, the resistance drop usually represents only a small percentage of the voltage held and therefore discrepancies between resistance characteristics amount to an extremely small percentage of the total voltage.

The voltage regulating relay setting is not explicitly stated, but 120 volts is implied because this is the reference voltage for testing the relay and it is also the base value for converting voltage errors to percentage values. In most cases the exact voltage level setting of the relay will have only a secondary effect on test results because they are the differences between voltages required to balance the relay with and without current in the compensator. However, since these are vector differences, the level setting of the relay will have some effect.

The selection of the mid-range setting as the test position for the compensator is somewhat arbitrary, but it seems to be the most representative single setting. Since dial marking errors are excluded from the accuracy determination, results for most practical types of compensators should be nearly proportional to the setting at other settings.

Recognized Errors. Compensators for modern single-phase regulators are usually provided with phase shift networks to obtain correct line drop compensation on 3-wire 3-phase systems without interconnecting the control circuits. The current supply and line drop compensator errors

are to be determined for each phase shift connection. The procedure outlined below is for the zero phase shift connection. For the 30 degree lag phase shift connection the procedure is repeated except that the current in the current transformer primary is shifted 30 degrees lag with respect to the voltage regulating relay potential from the angles required for the zero phase shift connection. Likewise, the procedure is repeated for the 30 degree lead connection except that the current is shifted 30 degrees lead from the angles required for the zero phase shift connection.

The only recognized sources of error are variations in magnitude of the load current and power factor of the load current. Errors in the resistance element and in the reactance element of the compensator are determined separately and the errors for combined resistance and reactance compensation are calculated from the individual errors. In determining accuracy the standards include compensation errors resulting from errors in the angle of compensation voltage, but exclude dial marking errors. This is discussed later.

A calibrated value for the mid-range setting of the resistance element is determined by test as the difference between the voltages required to balance the voltage regulating relay with zero regulator load current and with rated load current at unity power factor. (The reactance element is set on zero.) The actual change in applied voltage required to balance the voltage regulating relay as the load current is changed from zero to rated value at 80 per cent power factor is then determined by test or equivalent calculation. The error in the resistance element for rated current is the difference between the actual change in balancing voltage for 80 per cent power factor load current and the theoretically correct change computed for 80 per cent power factor based on the calibrated value. To insure obtaining the proper sign for the error the standards might be reworded to indicate more specifically that the difference should be taken as the "actual change minus the computed change" in voltage.

Errors in the resistance element for 25, 50, and 75 per cent rated load current at 80 per cent power factor are also determined in the same manner as for 100 per cent rated current, except that the calibrated values are determined by interpolation from the calibrated value for rated current instead of by direct test.

Calibrated values for the mid-range setting of the reactance element are determined in the same manner as for the resistance element except that zero power factor load current is used. Errors in the reactance element for each of the four values of load current at 80 per cent power factor are determined by the same procedure as for the resistance element.

Errors in the combined resistance and reactance elements could be determined by a procedure similar to that used for the individual elements. However, this would involve certain complications not encountered when dealing with the elements individually, and objections have been raised. One complication is that errors in the magnitudes of the resistance and reactance compensation voltages change the effective impedance angle of the combination to something other than 45 degrees. Unless the current was adjusted to a corresponding angle in determining a calibrated value for the combination these magnitude errors would appear in the error determined by this method, and it is not the intent of the standards to include magnitude, or dial marking, errors. Another complication is that the calibrated value method would yield zero error for a combination of resistance and reactance elements having equal magnitudes of compensation voltage and equal but opposite angular errors, although the actual result of such a combination is that the individual errors are additive. For example, consider a resistance element which produces exactly 12 volts compensation at the midposition but has an angle of plus five degrees instead of zero degrees, and a reactance element of exactly 12 volts but at 85 degrees instead of 90. When tested individually in accordance with the standards the error of the resistance element is plus 0.68 volt and the error of the reactance element is plus 0.89 volt. If tested in combination by the same method the resulting error would be zero because the impedance angle of the combination is 45 degrees. The balancing voltage for the voltage regulating relay would be 1.40 volts too high, but this would not appear as an error because the calibrated value for the combination would be correspondingly high.

As a simple approximation to the error of the combination of resistance and reactance elements, the standards use the algebraic sum of the errors for the individual elements. For the previous example, the sum is 1.57 volts, which is 0.17 volt greater than the actual error of 1.40 volts. If the reactance element had an angle of 95 degrees its individual error would be minus 0.89 volt. The algebraic sum of this error and the plus 0.68 volt error of the resistance element of the example is minus 0.21 volt. This is less than the actual error of minus 0.31 volt for the combination. Although the algebraic sum of the individual errors is not as accurate as may be desired it does more nearly represent the actual error of the combination of resistance and reactance than either of the individual errors or their arithmetic sum. Possibly a better proposal will be developed with actual usage.

Errors Excluded. The calibrated value method excludes magnitude or dial marking errors. The two principal arguments for this exclusion are that a dial marking error is readily compensated for by simply moving the dial to a position which gives the desired compensation voltage, and that on most distribution systems the final compensator setting is determined by trial. Where resistance and reactance elements are used in combination the same arguments might be applied to excluding angular errors except that correcting for angular errors is more involved.

Although the dial marking errors are not included in the over-all accuracy determination, the standards specify that such errors expressed as a per cent of 120 volts shall not exceed the per cent error permitted for the accuracy class of the associated regulator. This limit on dial marking error applies to any position of either the resistance or the reactance element with rated current in the compensator.

Determination of Maximum Plus and Minus Errors. The maximum plus error and the maximum minus error of the current supply and line drop compensator is determined for each phase shift connection. This is simply a matter of selecting the maximum plus and minus errors from the twelve errors determined for each phase shift connection. Errors in the resistance element are determined by test for each of four current values and likewise in the reactance element for each of four current values. Then errors for the combined resistance and reactance elements are calculated for each of the four current values as the algebraic sum of the errors in the individual elements.

By recognizing the maximum error found in either the resistance element alone, or the reactance element alone, or the two in combination, the standards obtain a value representative of about the worst error likely to be encountered in actual service. If only the error for combined resistance and reactance were recognized each element might have large errors, yet high accuracy would be indicated if the errors in the individual

elements offset each other. Such an accuracy classification would be misleading for installations where either predominately resistance or predominately reactance settings are used.

Accuracy Classes

Three standard accuracy classes of control devices for feeder voltage regulators are defined in Table I.

The sum of the plus errors and the sum of the minus errors is determined for each phase shift connection. The maximum of these sums is the over-all per cent error.

It is the intent of the standards that for each phase shift network connection the sum of the plus errors shall be obtained by adding the plus error of the potential supply and voltage regulating relay to the plus error of the current supply and line drop compensator with associated circuits. The plus error of the potential supply and voltage regulating relay is the sum of the plus errors due to regulator position (maximum raise to maximum lower), ambient temperature, frequency, and load current. The plus error of the current supply and line drop compensator is the maximum of the plus errors determined for resistance compensation, reactance compensation, or combined resistance and reactance compensation. The sum of the minus errors for each phase shift connection is to be determined in a like manner.

Potential Test Terminal Burden

Feeder voltage regulator control panels are usually provided with test terminals to which instruments can be connected to measure regulator output voltage. The standards state that connecting a burden of 25 volt-amperes at 0.7 power factor shall not change the test terminal voltage by more than plus or minus 1 per cent, unless otherwise specified. However, this deviation is not included in the specification of accuracy.

Some recording instruments impose a burden greater than 25 volt-amperes, and there may be occasions when it will be desired to connect more than one recording instrument to the same terminals. Some engineers might object to applying a correction of even one per cent to recording instrument charts. In this connection it should be noted that even though the recording instrument causes a voltage drop of one or two per cent in the control circuit and the regulator maintains a correspondingly higher line voltage, the chart obtained will show the voltage which will be maintained after the instrument is disconnected. Usually this is the record desired and no correction is needed. Of course, if a simultaneous recording is made at some other point on the feeder the two charts will not be directly comparable because of the temporarily high voltage held by the regulator. In such a case to obtain charts representing conditions after the instruments are disconnected, the correction should be applied to the chart obtained at the remote point, and not to the chart obtained at the regulator test terminals.

Table I

Accuracy Class	Over-all Per Cent Error
Class 1	plus or minus 1
Class 2	plus or minus 2
Class 5	plus or minus 5

Testing Facilities

Testing technique is beyond the scope of this paper. It is merely desired to emphasize the importance of extreme care and precision in measuring the accuracy of class 1 or class 2 control equipment. Since the sum of the several errors must be less than one or two per cent, each individual error must be much less, and this is beyond the accuracy of most ordinary instruments. Generally special set-ups will be required, even in well-equipped laboratories. Otherwise, the errors indicated may be due more to errors in measurement than to errors in the apparatus tested.

Many instrument problems will be encountered. For measuring voltage, accuracy at least equal to that of a laboratory standard type of voltmeter, ordinarily used for calibrating portable instruments, is required, and better accuracy is desirable. While assignment of this type of instrument to such usage may seem extreme, it should be recognized that many of the errors to be accurately determined are smaller than those found in many good portable instruments. In measuring frequency errors, it will usually be desirable to check several points over a range of several cycles and determine errors for the specified range from a carefully plotted curve. Really accurate measurement of power factor, or power factor angle, will be new to many laboratories.

Unusual stability of voltage and frequency will be required in power sources, and this must be obtained without distortion of voltage wave shape. Some means for indicating precisely when the voltage regulating relay contacts close is required; small 120-volt neon lamps have proved quite satisfactory for this purpose.

Conclusions

1. High accuracy control for feeder voltage regulators has real economic value in distribution systems.

2. Accuracy standards are much needed by utilities and manufacturers to obtain the desired results from the application of precise control equipment.

3. The proposed ASA standards are not yet perfected, but appear to offer a workable set of rules under which the industry can now operate and obtain the experience necessary to bring them into better form.

4. The measurement of errors in class 1 and class 2 control equipment will present problems which are new to many laboratories.

Definitions

"Band width" is used in the usual sense, that is, the difference between the high and low voltage limits maintained by a regulator for a particular set of conditions.

"Voltage level" is defined as the mean value of the band limit voltages.

"Errors" represent the deviation in voltage level from that for reference conditions for various other conditions of temperature, frequency, load or regulator position. It is here proposed to define "plus errors" as those causing the regulator to maintain a voltage level higher than the reference voltage and "minus errors" as those causing the regulator to maintain a voltage level lower than the reference value. This point is discussed under Summation of Errors for "Potential Supply and Voltage Regulating Relay."

Discussion

S. Minneci (General Electric Company, Pittsfield, Mass.): Birchard has indicated the economies that are possible with the use of precise control equipment. To realize these advantages, it is essential that the voltage regulating relays, which control the operation of the feeder voltage regulators, be carefully adjusted to maintain the system voltage within the required limits. It follows therefore that adjustments on these relays must be made with voltage-measuring instruments having a high degree of accuracy.

This precaution is particularly necessary when making adjustments out in the field where the conditions may be different from those encountered in the testing laboratories. The usual portable voltmeters may not be good enough for this purpose, as the errors introduced by their use may be considerably greater than those in the voltage regulating relay being adjusted. Indicating voltmeters with large and easy-to-read scales will be a great help in keeping the errors to a minimum.

Statistical Methods as Applied to the Manufacture and Testing of Wire and Cable

M. G. WOOLFSON
MEMBER AIEE

IT is now well established that many of the processes in the manufacture of wire and cable and tests of the finished product are amenable to control or study by recognized statistical methods. The scope of these applications is indicated in part by the following.

MACHINE CONTROL CHARTS (FOR MEASURABLE CHARACTERISTICS)

1. Weights per thousand feet of concentric stranded and crushed conductors.

2. Thicknesses of walls of paper and varnished cambric insulation.

3. Dimensions of extruded insulation.

4. Eccentricity and thickness of lead sheaths.

BAR CHARTS

1. Classified abnormalities found on inspection of adequate samples or large lots of finished product (single or multiple sampling method).

2. Causes of rejection in mass production operations.

FREQUENCY DISTRIBUTIONS (HISTOGRAMS)

1. Periodic summaries of the data used for plotting machine control charts, to show material usage, and actual frequency distributions of cumulative data, and to compare performance by shifts and by machines.

2. Studies by dimensions and/or weights of the component parts of finished products.

3. Summaries of continuing records of test data such as mutual capacitance of pairs of conductors in telephone cable, ionization tests of paper-insulated, oil-impregnated lead-sheathed cable, and physical tests of bare wire, rubber, and synthetic compounds.

P-CHARTS

(Fraction defective, that is, ratio of number of defective units to the total number under consideration.)

1. Preliminary and final electrical tests of rubber-insulated wires and cables.

C-charts showing the number of defects in samples of constant size, have been used on rare occasions. In general it may be said that so far as cable manufacturing is concerned they appear to have a somewhat limited value.

Machine Control Charts

From a practical standpoint machine control charts for $\bar{X}$ (the average or arithmetic mean of a set of observed values) and R (the range, the difference between the largest observed value and the lowest observed value in the set from which $\bar{X}$ is determined) have been found most satisfactory because of the facility with which they can be introduced and used. Furthermore, they have the advantage that personnel, directly concerned with statistical control of the product, can readily understand this particular form of chart.

Three-sigma upper and lower control limits are almost always used. Occasionally, however, for special reasons, it has been found expedient to establish arbitrary limits. Such alternative limits, which include manufacturing tolerances, are invariably set by the plant engineering department. Sample groups of four are used without exception. This makes for simplicity and for uniform practice when the same or similar products are fabricated in more than one plant. $\bar{X}$ and R levels and the corresponding upper and lower control limits are recalculated at least once each month.

Depending upon circumstances, control charts are applied to each individual machine in a given department or to all of the machines comprising a group; for example, when it can be demonstrated that all of the machines in a given group have about the same characteristics they are controlled as a unit using one chart. When different products fabricated in the same department on the same machines show similar performance as to any statistic, they also are controlled by means of one chart. The factors which enter into the problem of the number of charts required for effective control are many and varied, but with the objective and the influencing factors known the determina-

Paper 48-176, recommended by the AIEE subcommittee on statistical methods of the standards committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted November 10, 1947; made available for printing March 15, 1948.

M. G. WOOLFSON is manager of quality control for General Cable Corporation, New York, N. Y.

Figure 1. Continuous vulcanizing machine control chart. Over-all diameter, per cent of nominal

Figure 3. Continuous vulcanizing machine control chart. Tensile strength, per cent of minimum specified

tion is relatively simple. Several typical illustrations of the application of statistical methods to the control of processes in the manufacture of wire and cable and tests of the finished product are given later.

Control of Insulation Walls at Continuous Vulcanizing Machines

Figure 1 is a copy of an actual continuous vulcanizing machine control chart for $\overline{X}$ and R of over-all diameters in per cent of nominal for insulated wire (numbers 12 and 14 American wire gauge conductors with 2/64 inch of code rubber insulation). The chart covers a period of 29 successive days of operation and indicates a slight shift in $\overline{X}$ and R (averages of sets of $\overline{X}$ and R) and the corresponding upper and lower control limits from those assigned at the start of the period.

When control conditions exist, as they do substantially in this case, a specimen is taken from the finishing end of each fourth length of insulated wire for check of dimensions and for tensile strength test (in some cases, elongation). This provides a 25 per cent sampling of wire lengths. For purposes of charting, the observed data are accumulated in successive groups of four from which averages and ranges are obtained. If any plotted point falls outside of the control limits the department foreman takes necessary action to bring the operation again into control and sampling is simultaneously stepped up to 100 per cent of the wire lengths and so continued until control conditions are shown to have been again established.

Figure 2 is the corresponding machine control chart for minimum insulation thickness in per cent of the specified value. It is based on the identical specimens used in the construction of the chart, Figure 1. The same procedure as to control is used in both cases.

Tensile strength is measured using specimens from the same lengths as referred to before. The results obtained tend to be somewhat erratic because the specimens are not given sufficient time to become stable. They are, however, conservative.

Figure 3 is a control chart of tensile strength supplementing Figures 1 and 2.

Eccentricity and Average Thickness of Lead Sheaths

Two alternate methods are suggested for the control of eccentricity of lead sheaths.

1. Determining eccentricity of specimens (rings of lead) by taking 10 micrometer caliper measurements equally spaced circumferentially in accordance with the procedure outlined in the Association of Edison Illuminating Companies' specifications for Paper-Insulated, Lead-Covered Solid-Type Cable (seventh edition.) In this case eccentricity is computed using the formula

$$\text{Eccentricity per cent} = \frac{\text{Average} - \text{minimum}}{\text{Average}} \times 100$$

2. Visually examining the cut ends of the control specimens (rings of lead) to locate the thinnest and heaviest arcs and exploring these by micrometer caliper to obtain the actual minimum and maximum thickness. Eccentricity may then be computed using the formula derived from that in the preceding paragraph.

$$\text{Eccentricity per cent} = \frac{\text{Maximum} - \text{minimum}}{\text{Maximum} + \text{Minimum}} \times 100$$

Process control is a prerogative of the manufacturer and is in no manner restricted by the requirements of acceptance specifications in general use for finished products. This being so, the method of statistical control outlined in paragraph two has been chosen for the process inspection because it is less cumbersome in that it requires the recording

Figure 4. Machine control chart, vacuum-type lead press, per cent eccentricity

Figure 2. Continuous vulcanizing machine control chart. Minimum wall, per cent of nominal

Figure 3. Histogram, lead sheath eccentricity

of only two measurements and simpler calculations. However, in all acceptance inspections to establish conformance to specifications the mandatory method stated in paragraph one is used.

If the cross section of the core and the periphery of the cable itself are circular or nearly so, as for example for 1-conductor solid or oil-filled types, eccentricity will be theoretically the same when determined by either of the two alternate methods. However, when the cross section of the cable core is not quite circular, as may be so for multiconductor solid or type *H* constructions, discrepancies may be expected. In order to determine the magnitude of these discrepancies a group of specimens (rings of lead) taken one each from 475 cables for vacuum-type lead presses at two plants were measured by both methods. Averages for these determinations obtained (one) per method of paragraph one and (two) per method of paragraph two differed by only 0.55 per cent eccentricity.

For purposes of control of eccentricity a ring of lead is taken from each end of every manhole or stock length.

In order to show trends and current quality the observed data are accumulated in groups of four, for each of which $\overline{X}$ and R are obtained and plotted. Sheath extrusion is essentially a slow process, some cable lengths requiring many hours for lead covering. In order to reduce to a minimum the time required to obtain sufficient data for one point on the control chart, each group of four is made up of the last measurement obtained plus the three previous ones, that is, moving averages of and moving ranges of four are used. Table I, which is part of an actual inspection work sheet indicates clearly how this is accomplished.

Figure 4 shows a typical control chart for eccentricity of sheath extruded from a vacuum type lead press, for cables having cores exceeding 2.0 inch diameter, and sheaths of nominal average thickness greater than 95 mils. Several types of cables have been combined. The period covered by the chart is three consecutive days of operation. Fifty-seven individual determinations are involved. The gradual trend patterns of the successive plotted points are a consequence of using moving averages ranges, adjacent points are correlated. For independent groups of four values, as in the other control charts presented here, the points are independent.

Figure 6 Control of lead sheath thickness

Figure 5 is a histogram study of eccentricity of 675 specimens of sheath representing the entire output of one vacuum-type lead press in a typical period of approximately three months. Superposed on the histogram are the theoretical normal and skewed frequency distribution curves. These are shown respectively in the illustration as solid and broken lines.

In the control of eccentricity a skewed frequency distribution is to be expected because adjustments in the manufacturing process always aim to bring the values to zero.

Average sheath thicknesses in per cent of specified nominal are computed from maximum and minimum values referred to previously (see also Table I). The average $\overline{X}$ for these averages is determined frequently. Figure 6 sets forth $\overline{X}$ values weekly for a typical period of ten consecutive weeks.

Record of Tensile Strength of Code Rubber Compound

Figure 7 is a record, in the form of a tally sheet, of laboratory tests for tensile strength of specimens of finished building wire. Individual values are added as they are obtained. It will be recognized that this is not a chronological record in the same sense that a control chart is. Its construction is necessarily a slow process. After some time, however, a pattern develops and thereafter trends away from normality are quickly recognized. Modes are expected in this form of record, reflecting changes in the insulating compounds. Unless the chart is broken down separately, for each of its components, $\overline{X}$ values cannot be properly interpreted. The rejection limit per specifications, however, is significant.

Conclusion

Several examples of the application of statistical methods to the control of the manufacturing processes and to the tests of wire and cables have been outlined in this paper. These examples have been found useful in maintaining the quality of the finished products at high levels, and in assuring conformity to specification requirements in dimensions and other controllable characteristics.

Discussion

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): While the title of the paper gives no suggestion that the methods described by Woolfson have to do with quality control, his verbal presentation used that expression several times, so that it seems advisable to emphasize that the methods relate principally to quantity, rather than quality, control. This being the case, two results should be expected; assurance that dimensional specifications have been met, and reduction of waste in the use of excess material with consequent reduction of costs. I would be interested to hear whether the latter result has actually occurred.

Frequency Response Characteristics of Recording Instruments

TROY D. GRAYBEAL
MEMBER AIEE

Synopsis: Simple and direct methods are presented for ascertaining the magnitude of errors which arise from the dynamic limitations of instrument movements, and which appear in records obtained with recording instruments. Charts are given from which the a-c steady-state response may be obtained directly from the undamped natural frequency (or period) and the relative damping. These two basic constants of a particular instrument may be measured readily by the simple test methods described. Proper damping is emphasized, and certain techniques are suggested by which the frequency response may be improved beyond that obtainable with optimum damping. A simplified analysis of servo-actuated recorders suitable for application work also is included. The methods and the use of the charts presented are illustrated by means of numerical examples.

THE SUBJECT of recording instruments dates back to the early days in scientific work when it became necessary to measure quantities and to have a record which could be studied and analyzed after the measurements had been made. This subject is still of vital concern. It is essential that one know, at least to some degree, the accuracy of a record obtained from a recording instrument if the results are to be of value. The dynamic characteristics of instruments have been studied a great deal, and are quite well understood by the instrument manufacturers and by most research workers; but information dealing with this subject is not readily available in a form suitable for application work. It is the purpose of this paper to present in a simple and direct form information from which instrument errors in a given situation can be readily ascertained.

The large users of recording instruments are research laboratories and manufacturing plants, particularly refineries, chemical plants, and others which are commonly grouped under the heading of "process industries." The general trend in these industries, as well as in most others, is toward faster processes and higher speed devices to regulate them, since this in general means lower cost in production. High-speed recording is a very important aspect of this general trend. For many processes standard recording equipment is inadequate and special high-speed equipment is necessary. In others, standard equipment will suffice if properly adjusted.

For recording accurately at high speed, an instrument must have a high undamped natural frequency (low undamped natural period), and it must be properly damped. In fact, the accuracy of an instrument as related to the frequency of the signal it is recording may be expressed in terms of these two variables.

The undamped natural frequency depends upon the inertia of the instrument movement, and upon the spring constant of the restoring spring. Once an instrument is built, there is not much that can be done by the user of the instrument to increase the undamped natural frequency. The relative damping, on the other hand, is to a considerable degree under his control. Electrical instruments of the D'Arsonval type and some oscillographs obtain a considerable part of their damping effect from the electric circuit in which they are connected. Thus, the relative damping may be changed by changing the resistance of the electric circuit as seen from the terminals where the instrument is connected. In other oscillographs damping is introduced by submerging the element in oil, in which case the relative damping may be changed by the use of an oil of different viscosity. In other instruments damping is introduced by air vanes, and may be changed by adjusting the vanes. The damping of an instrument should be adjusted properly before other means to increase the frequency response are tried. Improper damping can easily account for a ten-to-one loss in frequency response.

Amplitude Response

In this paper, the amplitude response of an instrument is taken as the ratio of the recorded amplitude at a particular frequency to the recorded amplitude at zero frequency for the same amplitude of signal applied to the instrument in both cases, the basic signal being taken as a sine wave. Typical frequency response curves are illustrated in Figure 1 for different degrees of damping. The frequency is expressed as a fraction of the undamped natural frequency of the instrument, and the damping is expressed as a fraction of critical damping. Critical damping ($\beta = 1$) is defined in the usual way. It is the damping representing the transition case (as β is varied) from oscillatory to aperiodic motion following a sudden disturbance. Both ordinates and abscissa are nondimensional quantities and the curves are universally applicable to all instruments that may be considered as a linearly damped mass-spring mechanical system in which coulomb friction is assumed negligible.

The following salient features are evident from these curves:

1. For critical damping ($\beta = 1$) the instrument response is down 50 per cent at the undamped natural frequency; it is down one

Paper 48-172, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28–30, 1948. Manuscript submitted January 28, 1948; made available for printing March 29, 1948.

TROY D. GRAYBEAL is assistant professor of electrical engineering at the University of California, Berkeley, Calif.

The author wishes to express his gratitude to his colleagues and students for their help and suggestions with this work—in particular to A. G. Berger for aid in making calculations, to H. G. Wilson for preparing curves, to G. K. Tajima for tracing library and reference sources, and to F. E. Snodgrass for making tests and obtaining experimental data.

Figure 1. Nondimensional frequency response curves of an instrument

per cent at a frequency one-tenth the undamped natural frequency.

2. For a resonant peak to appear in the frequency response curve, the damping must be less than $1/\sqrt{2} = 0.707$ times critical damping.

3. For $\beta > 0.707$, the initial slope (slope at $=0$) of the frequency response curve is negative. This slope becomes zero (curve horizontal) for $\beta = 0.707$, and is positive (curve rises) for $\beta < 0.707$.

4. For accurate instrument response at the highest possible frequency, the relative damping should be near the value of 0.707.

For predicting the maximum frequency that an instrument will record with an error not greater than some specified amount, or for ascertaining the error at a given frequency, the curves of Figure 2 have been prepared. Relative damping β is taken as abscissa, and frequency expressed as a fraction of the undamped natural frequency is taken as ordinates. The curves represent loci of constant amplitude error. The range of relative damping is restricted to values of β from 0.1 to 10. For small values of β, the curves approach limiting values which may be taken as the values for $\beta = 0.1$. For values of β greater than ten, the effect of the inertia of the instrument is negligible, and the maximum frequency for a specified error may be ascertained more easily by a method to be explained later. The break in the curves near $\beta = 0.707$, arises because of the rising nature of the frequency response curves for $\beta < 0.707$. If the maximum error is specified as say ± 3 per cent (see Figure 1), the instrument may be damped to a value $\beta = 0.613$, and the resonant rise at $f/f_n = 0.5$ will not be greater than three per cent. Therefore the frequency limit for this value of β will be $f/f_n = 0.78$ where the response is down three per cent. If β be reduced below this value, the resonant rise will be greater than three per cent, and the limit of f/f_n will therefore be less than 0.50, making an abrupt break in the corresponding error locus curve at $\beta = 0.613$. The abrupt break for any curve of Figure 2 occurs for the value of β which makes the resonant rise at the peak equal to the per cent error represented by the particular error locus curve.

For slow variations, frequencies less than one cycle per second or so, it is usually more convenient to work with periods rather than frequencies. The curves of Figure 3 present the same information as those of Figure 2, except that the ordinates represent periods. The period is expressed in nondimensional form as a fraction of the undamped natural period of the instrument in order that the curves be universally applicable.

Phase Error

While the amplitude error is usually of major concern, there are times when the phase error of an instrument need be considered. The phase error arises because the motion of the instrument pointer does not exactly follow the variations in the quantity being measured. For a sinusoidally varying quantity, the instrument pointed will lag behind and reach the peak of its swing at a time later than the peak of the varying quantity being measured. This is true even though the damping is low and the amplitude response is greater than 100 per cent. This lag can be measured conveniently in degrees, a degree representing 1/360 part of one complete cycle of variation. The phase error is always a lagging angle and becomes 90 degrees at the undamped natural frequency regardless of the degree of damping. In general the phase error will be greater for frequencies below the undamped natural frequency when the damping is increased. Figure 4 gives the phase angle error for different values of β plotted against frequency.

For values of $\beta \geq 0.707$, the amplitude response is too small. The error in this case may be taken as positive. For a given relative frequency and degree of damping, the amplitude error and phase error are uniquely determined. Thus it is possible to plot curves of phase error versus amplitude error for different relative dampings. One of these variables may then be found if the other two are known. Such a set of curves is given in Figure 5. For large values of β, the curve assumes a limiting position. For values of $\beta < 0.707$, the amplitude error becomes negative and cannot be plotted as such on a log scale. If plotted as a positive quantity, the curve has three branches, and it is then necessary to know the relative frequency to know which branch applies. As the use of such multivalued curves is confusing, they have been omitted. The phase angle error for values of $\beta < 0.707$ may be obtained from the curves of Figure 4.

Illustrative Example

A recording instrument having an undamped natural period of 0.5 second is damped to a relative value $\beta = 1.5$. It is recording a signal which goes through one complete cycle in a sinusoidal manner in three seconds. How much error exists in the record obtained? Can the instrument be adjusted to give a record accurate to one per cent? If so, what is the maximum relative damping permissible, and what is the phase error under these conditions?

Solution:

$T/T_n = 3/0.5 = 6$
$f_n = 1/0.5 = 2$ cycles per second
$f = 1/3 = 0.3333$ cycle per second
$f/f_n = 0.1667$

From Figure 2 (or Figure 3) the error in the record obtained is nine per cent, the recorded value being too low.

From Figure 2 (or Figure 3), if the damping were reduced to 0.82, the error in the record obtained would be reduced to one per cent.

The phase error is 16 degrees lagging from Figure 4 (or Figure 5) for a relative damping 0.82 and an error of one per cent.

Highly-damped Instruments

When an instrument is highly damped, the component of force which arises from the inertia of the moving system is small compared with other forces and may be neglected for frequencies below the undamped natural frequency. Under these conditions the a-c steady-state response may be computed on the basis of equation 24, and the error on the basis of equation 31 of the Appendix. Equation 24 is plotted in Figure 1 as dotted lines for values of $\beta=1$ (critical damping), $\beta=2$, and $\beta=3$ for comparison with those plotted in solid lines from the exact expression which includes the inertia term.

The error computed on the basis of the approximate expression is $2\beta^3/(2\beta^2-1)$ times the error computed on the basis of the exact expression for small errors. Thus an instrument may be considered highly damped if β is greater than about two or three. For example, if the error were one per cent on the basis of the exact expression for $\beta=2$, the approximate expression would give an error of $8/7\times1$ per cent $=1.14$ per cent. If $\beta=3$, the agreement would be much better $18/17\times1$ per cent $=1.06$ per cent. This would probably be close enough for most instances in practice. The approximate expression always gives results on the conservative side.

For high damping, the maximum frequency an instrument will record with an error not greater than some specified amount may be obtained from the curves of Figure 2 or Figure 3 if the relative damping and the undamped natural frequency are known and if $\beta<10$. If $\beta>10$, or if β and f_n are not known independently, the curves of Figure 6 or Figure 7 may be used. In these curves ΔT is a new variable being defined as the time required for the instrument to reach 50 per cent of its final steady-state deflection after a sudden step-function disturbance. ΔT may be computed from β and f_m (or T_n) if these are known.

$$\Delta T=0.2205\beta/f_n$$

or

$$\Delta T=0.2205\beta T_n \qquad (40)^*$$

*(See numbered equations in Appendix)

Illustrative Example

An instrument having an undamped natural period of 0.5 second is damped to a relative value $\beta=4.5$. What is the minimum period of an a-c signal that can be recorded with an error not exceeding five per cent?—one per cent?

Solution:

$$\Delta T=0.2205\ (4.5)\ 0.5=0.496 \text{ second}=496 \text{ milliseconds}$$

From Figure 7: Minimum period for five per cent error $=13.5$ seconds. Minimum period for one per cent error $=31$ seconds.

These values may be checked from the curves of Figure 3: Minimum period for five per cent error $=0.5\ (27.0)=13.5$ seconds; for one per cent error $=0.5\ (62)=31$ seconds.

Determination of Instrument Constants by Test

In order to use the curves of Figures 2 to 7, it is necessary to know the constants

Figure 2. Amplitude error curves of an instrument in terms of frequency

Figure 3. Amplitude error curves of an instrument in terms of period

of the instrument β and f_n, or ΔT if the relative damping is known to be at least two or three times critical damping. The constants may be found from either a-c steady-state response tests, or from transient tests. The particular method which is most convenient will depend upon the auxiliary attachments built into the particular instrument being tested, as well as upon the type of testing equipment available. The results obtained by some methods are less subject to errors arising from imperfections of the instrument, notably friction introduced by the pen moving on the chart, and would be preferred where a choice of methods is available. Two or more methods might be used and the most probable values of β and f_n selected on the basis of judgment if the constants need be determined with a high degree of accuracy. In most applications, however, this is not necessary.

If equipment is available for a-c steady-state response tests, the frequency response may be obtained directly from such tests. The test equipment required, however, is much more elaborate than that required for transient tests, and for this reason the latter probably would be used more often. Many recorders are provided with chart drives which may be driven fast enough to obtain transient response curves of the instrument directly with essentially no auxiliary apparatus. With D'Arsonval-type movements and others in which the damping is affected by the system in which the instrument is to be used, the direct measurement of a-c response requires that a dummy system be used in the test set-up which matches the characteristics of the actual system; otherwise corrections or modifications in the data obtained must be made. These modifications can be made most effectively by computing f_n and β_o directly from test data. β_o is the relative damping inherent in the instrument itself. These values then would be used in the same manner as those obtained from transient data for predicting the performance of the instrument in the system in which it would be used. Some transient methods have the advantage that the transient response tests may be made with the instrument connected into the system with which it is used, and the value of relative damping β obtained includes the component reflected into the instrument by the system.

A-C Steady-State Methods

The undamped natural frequency f_n can be found by applying an a-c signal to the instrument and adjusting the frequency of the signal until the applied signal and the motion of the instrument pointer are 90 degrees out of phase. The frequency of the applied signal is then equal to f_n. This method of finding f_n is independent of the relative damping. The relative damping then may be found by measuring the per unit response (actual response divided by signal amplitude, both expressed in the same units) at some frequency less than or equal to f_n and applying equation 7 of the appendix. The chief disadvantage of this method arises from the practical difficulties of measuring the phase between the applied signal and the motion of the instrument pointer. A stroboscope is often useful for this measurement.

If the instrument has inherent damping which is less than 0.707 times critical damping, the resonant frequency and the per unit response at the resonant frequency may be obtained from a frequency response curve. The undamped natural frequency then may be found from equation 10 and the relative damping from equation 11 of the Appendix. This method gives good results for $\beta<0.6$ where the resonant peak is sufficiently sharp for accurate determination of the resonant frequency f_r. One major limitation of this method is that many instruments have inherent damping greater than 0.707 and the method is not applicable.

Transient Methods

Method 1. If the damping is less than critical damping, β may be found from the ratio of successive positive and negative swings in accordance with equation 21 which is plotted in Figure 8. The undamped natural frequency then may be obtained from the frequency of the damped oscillation by means of equation 9. This equation also is plotted in Figure 8. This method gives good results for β less than about 0.8, but is subject to some error from pen friction. The effect of pen friction is to clip off the peaks of the swing so that the numerical value of X_o/X_1 obtained is somewhat too large. The effect is not serious, however, since a large change in the value of X_o/X_1 results in a comparatively small change in β. For instance, if $X_o/X_1=20$, $\beta=0.69$. If X_o/X_1 is increased to 30, an increase of 50 per cent, β increases to 0.77, about 12 per cent. If β is greater than about 0.8, the amplitude of successive swings decreases by such a large ratio that it is impossible to determine even the order of magnitude of X_1 from the chart record, particularly

Figure 4 (left). Phase error curves of an instrument in terms of frequency

Figure 5. Phase error curves of an instrument in terms of amplitude error

For relative damping less than 0.707, the curves of Figure 4 may be used

Figure 6 (left). Amplitude error curves for highly-damped instruments in terms of frequency

Figure 7. Amplitude error curves for highly-damped instruments in terms of period

if there is any appreciable pen friction; so that the method is not applicable for values of relative damping near the critical value. In some galvanometers, the damping inherent in the instrument is very low and X_o and X_1 are very nearly equal, thus making it difficult to determine β accurately. This difficulty may be overcome by computing the ratio of decay over several swings of the instrument. Thus if n swings are considered (each positive and negative swing count), the "n"th root of this ratio would be computed and this value used to enter the curves of Figure 8.

Method 2. As explained in the Appendix, the actual shape of the transient response curve depends only upon the relative damping, while the time required for a certain change in deflection to occur depends primarily upon the undamped natural frequency. Making use of this fact, the curves of Figure 9 have been prepared. T_1 is the time required for the deflection to reach 50 per cent of the final steady-state value, while ΔT is the time increment for the deflection to decrease from 50 per cent to 25 per cent of its final steady-state value. By computing the value of $\Delta T/T_1$ from the transient response curve, the relative damping can be found from the curve $\Delta T/T_1$. The value of f_nT_1 can be found from the other curve. From this value and the actual time value of T_1 from the transient response curve, the undamped natural frequency f_n can be computed. This method gives fairly good results for $0.8 < \beta < 2$ if pen friction is not too great. This method is more subject to pen friction error than *Method 1*. For this reason, it is often desirable to obtain the relative damping β_o for the instrument on open circuit, if a D'Arsonval type, and to correct this value to take into account the damping effect introduced by the circuit in which the instrument is connected. A method of doing this is described later.

An important source of error is the limit of accuracy of making measurements on the chart, and the fact that the circular cross rulings on the chart usually do not correspond accurately with the arc described by the pen of the instrument. This latter effect can be checked by allowing the pen to swing over the chart while the chart is stationary, and allowance may be made for it if appreciable.

An idea of the degree of accuracy that may be obtained practically by the two methods outlined is illustrated by the curves of Figures 16 and 17. The 5-milliampere instrument is a "standard" commercial instrument, while the 3-milliampere instrument is classified as a high-torque instrument. The effect of pen friction is much greater for the 5-milliampere instrument. This fact accounts for the greater discrepancy between points obtained from transient records and the computed curve. For the 3-milliampere instrument, the discrepancy is due principally to the limit of accuracy of making measurements on the chart. The effect of pen friction on the a-c steady-state response is illustrated by the curve for 10,000 ohms in Figure 14. The instrument was damped slightly below 0.707, so that a slight rise would be expected in the frequency response curve. The response actually drops about 1.5 per cent at a frequency of 0.2 cycle per second principally because of pen friction, and then rises to 99 per cent response at 0.6 cycle per second before dropping off as the undamped natural frequency is approached. This pen friction effect is not noticeable in the curves of Figure 13 which were obtained on the high-torque instrument. In obtaining these response curves, a signal corresponding to 80 per cent of the full scale amplitude was used. For smaller amplitudes, the percentage effect of pen friction would be much greater. This effect also varies with chart speed.

Method 3. For values of relative damping greater than about two, the ratio $\Delta T/T_1$ is very nearly unity, and the curves of Figure 6 or 7 may be used to obtain the a-c steady-state frequency error directly. For values of β near two where

Figure 8. Curves showing the relationship between relative damping and the ratio of successive swings; and between relative damping and the ratio of the damped and undamped natural frequencies of underdamped instruments

Figure 9. Curves showing the relationship between relative damping and the ratio of the time required for the deflection to become 50 per cent of the final value to the time increment for the deflection to decrease from 50 to 25 per cent of the final value; and between the relative damping and the product of the undamped natural frequency and the time required for the deflection to become 50 per cent of the final value

there is appreciable difference between T_1 and ΔT, ΔT should be used for entering the curves of Figures 6 and 7.

Illustrative Example

An instrument having the characteristics illustrated in Figure 11 operates in a circuit having a driving point resistance of 10,000 ohms. What is the maximum frequency the instrument will record with an error not greater than 2 per cent? What will be the maximum frequency if the circuit resistance is 4,000 ohm?—zero ohms?

Solution:

Method 1.

For the case with 10,000 ohms resistance $X_o = 1.00$, $X_1 = 0.060$, and $f_d = 1.97$ cycles per second by measurements made directly on the chart record.

$X_o/X_1 = 16.7$. From curves of Figure 8, $\beta = 0.67$, $f_n/f_d = 1.35$.

From these values, $f_n = 1.35\ (1.97) = 2.66$ cycles per second.

From curves of Figure 2, $f/f_n = 0.60$.

The maximum frequency for which the error will not exceed two per cent is therefore $0.60\ (2.66) = 1.58$ cycles per second.

Method 2.

	For 10,000 Ohms	For 4,000 Ohms	For Zero Ohms
Measurements taken directly from chart records	$T_1 = 0.085$ second	0.105 second	0.267 second
	$\Delta T = 0.038$ second	0.064 second	0.258 second
Computing the ratio	$\Delta T/T_1 = 0.448$	0.610	0.957
From Figure 9	$\beta = 0.69$	1.02	3.0
	$f_nT_1 = 0.225$	0.270	0.67
Dividing f_nT_1 by T_1	$f_n = 2.65$ cycles per second	2.58 cycles per second	2.50 cycles per second
From curves of Figure 2	$f/f_n = 0.5$	0.17	0.035
Maximum frequency for 2 per cent maximum error is	1.32 cycles per second	0.44 cycles per second	0.0875 cycle per second

Method 3.

For the case with zero external resistance, the value of maximum frequency could be obtained more readily from Figure 6. Using the value of $\Delta T = 0.258$ seconds, the maximum frequency for two per cent maximum error is 0.087 cycles per second.

The values computed in this example may be compared with the frequency response curves shown in Figure 13 which were obtained on the same instrument by actual test.

Component of Relative Damping Reflected From the Electrical Side—D'Arsonval Movement

It is shown in the Appendix that for a D'Arsonval-type instrument, the relative damping β consists of two components, one which represents the damping inherent in the movement when the coil circuit is open (β_o) and another component which is inversely proportional to the resistance of the coil circuit (β_1).

$$\beta = \beta_o + \beta_1 \tag{56}$$

where

$$\beta_1 = F/R_T \tag{59}$$

$$F = 9.8\pi l K f_n \times 10^{-8}/(I_p)^2 \tag{60}$$

Equation 59 is plotted in Figure 10 with β_1 as a parameter. These curves may be used for computing the component of damping which is reflected into the mechanical system of the instrument from the electrical circuit in which the instrument is connected. This component of relative damping when added to the component of relative damping inherent in the instrument movement gives the relative damping of the instrument. To compute the factor F, one needs to know the undamped natural frequency of the instrument, the coil current for full scale deflection, the length of arc on the chart which represents full scale, and the force that must be exerted at the writing point of the pointer to cause full scale deflection. If the instrument is shunted, the shunt must be considered as part of the network into which the instrument is connected. That is, the current I_p is the current for full scale deflection which actually flows in the moving coil of the instrument. The parameter R_T is the actual coil resistance plus the resistance of the network and the resistance of the shunt combined in parallel.

Illustrative Example

An instrument is internally damped (value of damping when coil circuit is

open) to a relative value of 0.37. The undamped natural frequency is 2.60 cycles per second, the resistance of the moving coil is 1,324 ohms, the current range is three milliamperes, the length of the chart scale is 12 centimeters, and the force that must be applied at the end of the pointer to produce full scale deflection is 3.26 grams. The instrument is not shunted. What must be the resistance of the external circuit to give critical damping?—70 per cent critical damping?

Solution:

$$F = \frac{9.8\pi(12)\ 3.26\ (2.60)\ 10^{-4}}{(0.003)^2} = 3{,}480$$

For critical damping, $\beta_1 = 1 - 0.37 = 0.63$.

From Figure 10, $R_P = 5{,}520$ ohms and the external circuit resistance $= 4{,}200$ ohms.

For 70 per cent critical damping, $\beta_1 = 0.70 - 0.37 = 0.33$.

From Figure 10, $R_T = 10{,}530$ ohms and the external circuit resistance $= 9{,}210$ ohms.

Application of Curves to Systems Other Than Recording Instruments

The curves presented in Figures 2 to 9 are applicable to any type of mechanical system which may be represented by a second order differential equation. Such a list would include galvanometers, oscillograph elements, liquid level gauges, pressure gauges, as well as the simpler types of servomechanisms.

Methods of Increasing Frequency Response

In applications where the frequency response of an instrument is not fast enough to give a sufficiently accurate record, the response may be improved in several ways, but usually at a sacrifice in sensitivity.

Any practical solution usually represents a compromise between these two conflicting factors. As a rule a D'Arsonval-type movement should not be shunted except by comparatively high-resistance networks if the maximum frequency response capabilities of the instrument are to be realized.

In making adjustments to increase frequency response, the first consideration should be given to damping. Unless the damping is adjusted closely to the optimum value, a considerable loss in frequency response will result. For instance, if an instrument having an undamped natural frequency of one cycle per second is damped to a relative value of 0.67, it will record a frequency of 0.5 cycle per second with an error not greater than one per cent. But if the damping is increased to critical damping, the maximum frequency that can be recorded with an error not greater than one per cent is only 0.1 cycle per second. Thus, if an instrument is damped to the critical value, the frequency response can be improved by a five-to-one ratio by adjustment of damping.

If the frequency response of an instrument must be improved beyond that which can be achieved by optimum damping, special techniques must be resorted to. Some improvement may be achieved by replacing the restoring springs of the instrument movement with springs having a larger spring constant. This, of course, will reduce the sensitivity of the instrument. If this loss of sensitivity is not objectionable, still the improvement that can be achieved in this way probably would never be greater than about a two-to-one ratio. For a two-to-one improvement, the moving coil of the instrument would have to carry four times the original current for the same deflection

Figure 10 (left). Curves showing the relationship between the component of relative damping reflected from the electrical circuit of a D'Arsonval-type movement, the resistance of the coil circuit of the instrument, and the "Conversion" factor F

Figure 11. Transient response curves of a 3-milliampere recording milliammeter

Figure 12. Transient response curves of a 5-milliampere recording milliammeter

Figure 13. Frequency response curves of a 3-milliampere recording milliammeter obtained by actual test

Figure 14. Frequency response curves of a 5-milliampere recording milliammeter obtained by actual test

Unless the coil originally were designed very conservatively, even a four-to-one increase in the coil current might be sufficient to damage the coil from overheating.

The frequency response of D'Arsonval-type movements may be increased by the use of special coupling networks connected between the circuit where the measurement is to be made and the coil circuit of the instrument. The simplest network of this type is an inductive shunt connected across the instrument coil terminals. By the proper choice of the resistance and inductance of this shunt, the frequency response may be increased considerably if the instrument is supplied from a comparatively high impedance source, but at a considerable sacrifice in sensitivity.

Theoretically, networks can be devised which will give any desired increase in frequency response; but the greater the increase in response, the greater the sacrifice in sensitivity. Vacuum tube amplifiers might be included in the coupling network to overcome the loss in sensitivity, but the upper limit of frequency response attainable is usually limited by the maximum permissible heating in the instrument coil. In general, when special coupling networks are used with an instrument, the curves given in this paper do not apply, because the differential equations defining the behavior of the system are of a higher degree than the second. The behavior of such systems can be studied experimentally, or analytically, by setting up the equivalent circuit of Figure 15 for the instrument in question. The coupling network would be connected in series with $E(t)$, and the current i_L would be studied as a function of frequency.

Servo-Actuated Recorders

There are available at the present time a number of different types of servo-actuated recorders mostly in the form of self-balancing potentiometers. These instruments require a relatively small signal, of the order of one per cent to five per cent of full scale, to produce maximum velocity of the recording pen. The time T_{fs} required for the pen to move from one end of the chart to the other under this condition is a standard specification of such instruments, and can be used for estimating the maximum frequency, or minimum period, which the instrument will record accurately. A simplified analysis which neglects any error introduced by the servomechanism itself is given in the Appendix. Curves based on this analysis are given in Figure 18 with T_{fs} as a parameter. Although the curves neglect lags in the servomechanism of the instrument, they are sufficiently accurate for ascertaining whether a particular instrument is suitable for a particular application. This is true because one wishes to know the order of magnitude of the minimum period the instrument will record accurately rather than the value of this minimum period to a high degree of accuracy. The curves given in Figure 18 are based on sine waves simply because this is one convenient method of presenting the information. When the instrument is recording irregular wave forms, the fundamental limitation is the maximum rate of change of the signal being recorded, and not the fact that it contains harmonics as is the case with most other types of instruments. An example will illustrate the use of the curves.

Illustrative Example

A servo-actuated self-balancing potentiometer requires three seconds for the pen to move from one end of the chart to the other with maximum signal applied. The recorder is to be used to record a signal which has a period of five seconds and which varies in a sinusoidal manner. What is the maximum peak-to-peak amplitude on the chart for which the instrument will record this signal accurately?

Solution:

$T_{fs} = 3$ seconds

From Figure 18, scale B, the maximum peak-to-peak amplitude permissible is 53 per cent. The sensitivity of the recorder would have to be adjusted by means of an external voltage divider or similar method so that the maximum signal available would not drive the pen over more than 53 per cent of the chart range. If the full width of the chart were to be utilized, an instrument having a value of T_f, not greater than 1.6 seconds would have to be used.

Conclusions

The chart methods presented in this paper provide a simple and direct method of predicting either the magnitude of errors in records obtained with recording instruments when recording a-c quantities or the maximum frequency that a particular instrument will record if the error is not to exceed some specified maximum per cent error.

The behavior of most instruments can be defined by a second order differential equation. In this case the frequency response characteristics can be expressed in terms of the undamped natural frequency and the relative damping. The maximum frequency that an instrument will record accurately is critically dependent upon the relative damping. A sacrifice of ten-to-one or more in frequency response may result if the damping is improperly adjusted. The relative damping should be somewhat less than 0.7 for

maximum frequency response, the exact value being determined by the maximum error that can be permitted in the record obtained.

The undamped natural frequency and relative damping may be measured by a-c steady-state or transient test methods. Transient tests usually require less complicated testing equipment, and for this reason methods based upon transient tests usually are preferable. The values of undamped natural frequency and relative damping obtained by test methods are subject to some error from imperfections of the instrument, notably friction between the pen and chart, as well as from the limit of accuracy of making measurements on chart records. The former is not serious in a well designed properly adjusted instrument, and the latter may be minimized by the choice of a suitable chart speed.

For instruments in which the relative damping is affected by the system in which the instrument is connected when making measurements, the relative damping usually may be obtained more accurately by measuring the relative damping inherent in the instrument itself, and adding to this value the component of relative damping reflected into the movement by the system with which the instrument is used. For D'Arsonval-type movements, the component of relative damping reflected from the electrical circuit of the instrument is inversely proportional to the coil circuit resistance. The proportionality of "conversion" factor may be computed from the undamped natural frequency, the coil current for full scale deflection, the length of the arc on the chart which represents full scale, and the force that must be exerted at the writing point of the pen to cause full scale deflection.

If the relative damping is greater than about two or three, the component of force arising from the inertia of the instrument movement may be neglected for frequencies less than the undamped natural frequency. The frequency response characteristics then may be expressed in terms of ΔT, the time required for the pointer deflection to assume 50 per cent of its final steady-state deflection following a step-function disturbance. The parameter ΔT may be computed from the relative damping and the undamped natural frequency, or it may be obtained directly from a transient test.

It is possible to increase the frequency response of an instrument beyond that obtainable with optimum damping, either by making modifications in the instrument movement to increase the undamped natural frequency, or, for D'Arsonval-type movements, by the use of coupling networks between the coil circuit of the instrument and the network where the measurement is to be made. Both these methods represent a sacrifice in sensitivity. The upper limit that can be achieved practically depends upon the maximum permissible coil current that will not damage the coil of the instrument from overheating.

For those types of servo-actuated recorders where a signal of the order of one per cent to five per cent of full scale will give maximum velocity of the recording pen, the upper limit of frequency for which the recorder will give an accurate record may be expressed in terms of the time required for the pen to move from one end of the chart to the other at maximum velocity. The results obtained from this simplified analysis are sufficiently accurate for application work.

Appendix

A-C Steady-State Solution

The differential equation of motion of the instrument movement may be written

$$M\frac{d^2X}{dt^2}+C\frac{dX}{dt}+KX=f(t) \tag{1}$$

where M, C, K, and X may be expressed in any consistent system of units, either translational or rotational. Dividing by M and writing p for d/dt:

$$\left(p^2+\frac{C}{M}p+\frac{K}{M}\right)X=\frac{1}{M}f(t) \tag{2}$$

which reduces to:

$$(p^2+2\omega_n\beta p+\omega_n^2)\,X=\frac{1}{M}f(t) \tag{3}$$

by substitution of

$$\omega_n=\sqrt{K/M}=\text{Undamped natural angular velocity} \tag{4}$$

$$\beta=C/C_c=\frac{C}{2\sqrt{MK}}=\frac{\text{Damping coefficient}}{\text{Critical damping coefficient}} \tag{5}$$

The steady-state solution in vector form for a sinusoidal driving force equal to 100 per cent amplitude is[8]:

$$Y=\frac{1}{\sqrt{(1-\omega^2/\omega_n^2)^2+(2\beta\omega/\omega_n)^2}}\Bigg|\underline{-\tan^{-1}\frac{2\beta\omega/\omega_n}{1-(\omega/\omega_n)^2}} \tag{6}$$

$$Y=\frac{1}{\sqrt{(1-f^2/f_n^2)^2+(2\beta f/f_n)^2}}\Bigg|\underline{-\tan^{-1}\frac{2\beta f/f_n}{1-(f/f_n)^2}} \tag{7}$$

(amplitude) (phase)

in which the undamped natural frequency

$$f_n=\frac{1}{2\pi}\sqrt{\frac{K}{M}} \tag{8}$$

the damped natural frequency

$$f_d=f_n\sqrt{1-\beta^2} \tag{9}$$

the resonant frequency

$$f_r=f_n\sqrt{1-2\beta^2} \tag{10}$$

The steady-state response at the resonant frequency

$$=\frac{1}{2\beta\sqrt{1-\beta^2}}\quad\beta<1/\sqrt{2}=0.707 \tag{11}$$

The amplitude as given by equation 7 is plotted in Figure 1 (solid lines) for different values of β. The phase is plotted in Figure 4. Figure 5 is a cross plot of $(1-|Y|)$ and phase (Y) for $\beta\geq0.707$.

Transient Solution

The response of the instrument movement to a sudden step function disturbance, no driving force but with an initial displacement, is defined by the differential equation:

$$(p^2+2\omega_n\beta p+\omega_n^2)X=0 \tag{12}$$

and boundary conditions:

at $t=0$, $X=100$ per cent and $dX/dt=0$

Solutions:

Underdamped case, $\beta<1$

$$X=\frac{1}{\sqrt{1-\beta^2}}\,\epsilon^{-\beta\omega_n t}\sin\left[\sqrt{1-\beta^2}\,\omega_n t+\phi\right] \tag{13}$$

where

$$\tan\phi=\frac{\sqrt{1-\beta^2}}{\beta} \tag{14}$$

Critically-damped case, $\beta=1$

$$X=(1+\omega_n t)\,\epsilon^{-\omega_n t} \tag{15}$$

Overdamped case, $\beta>1$

$$X=\frac{\beta+\sqrt{\beta^2-1}}{2\sqrt{\beta^2-1}}\,\epsilon^{-(\beta-\sqrt{\beta^2-1})\omega_n t}-\frac{\beta-\sqrt{\beta^2-1}}{2\sqrt{\beta^2-1}}\,\epsilon^{-(\beta+\sqrt{\beta^2-1})\omega_n t} \tag{16}$$

$R_1 = R_2$ OHMS

$C_1 = \frac{M}{U_E U_M}$ FARADS

$R_2 = \frac{U_E U_M}{C}$ OHMS

Figure 15. Equivalent circuit which represents a D'Arsonval-type instrument

Relationship Between Successive Positive and Negative Peaks for Underdamped Case

$$D = \frac{\text{any maximum}}{\text{the next following minimum}}$$

$$= -\epsilon^{\frac{\pi\beta}{\sqrt{1-\beta^2}}} \qquad (19)$$

This ratio is exact and does not depend upon ϕ. Disregarding the negative sign:

$$\ln D = \frac{\pi\beta}{\sqrt{1-\beta^2}} \qquad (20)$$

which solved for β gives:

$$\beta = \frac{\ln^2 D}{\sqrt{\pi^2+\ln^2 D}} \qquad (21)$$

This equation is plotted in Figure 8, in which $D = X_2/X_1$.

Relationship Between Damped Natural Frequency and Undamped Natural Frequency

From equation 9

$$\frac{f_d}{f_n} = \sqrt{1-\beta^2} \qquad (22)$$

This equation is plotted in Figure 8.

Auxiliary Curves for the Determination of β

In equation 13, $\omega_n t$ may be replaced by another variable say Z:

$$X = \frac{1}{\sqrt{1-\beta^2}}\epsilon^{-\beta Z}\sin\left[Z\sqrt{1-\beta^2}+\phi\right] \qquad (23)$$

in which case ω_n and t both disappear. This means that the shape of the curve is independent of ω_n, since if ω_n is doubled, the time scale may be doubled (each scale unit representing half the time) and the two curves will be identical. The shape of the curve is determined completely by β, and its time calibration by ω_n.

One may compute β by any convenient method which depends upon the shape of the curve, and not upon its time calibration. The same statements also apply for the critical and overdamped solutions, equations 15 and 16. To cover the range of values of β near the critical value where the log decrement, equation 21, does not yield accurate results on the underdamped side and where the approximate method to be described later does not yield reliable results on the overdamped side, the ratio of the time required for the displacement to reach 50 per cent of its final value and the time increment required for the displacement to decrease from 50 to 25 per cent of its final value, $T_1/\Delta T$, is used as a parameter for finding β. Values of T_1 and ΔT were obtained by solving equations 13, 15, and 16 by trial for different values of β from 0.5 to 5. The resultant curve of $\Delta T/T_1$ is plotted in Figure 9, together with a curve of f_nT_1, both as functions of β. From a transient response curve of an instrument, the value of β for the instrument can be found from the curve $\Delta T/T_1$; and the value of f_nT_1 obtained from the other curve enables one to compute f_n from the time calibration of the transient record.

Approximations for Heavy Damping—Steady-State Frequency Response Curves

For large values of β, equation 7 may be written:

$$Y \approx \frac{1}{\sqrt{1+4\beta^2(f/f_n)^2}} \qquad (24)$$

This equation is plotted in Figure 1 (dotted lines) for $\beta = 1, 2, 3$ for comparison with the corresponding curves plotted from equation 7.

For small errors, the error obtained on the basis of equation 24 may be compared with that obtained on the basis of equation 7 by making use of series expansions. From equation 7

$$Y_{\text{exact}} = 1-(2\beta^2-1)(f/f_n)^2 + (1-6\beta^2+6\beta^4)(f/f_n)^4 \ldots \qquad (25)$$

$$\xi_{\text{exact}} = \text{error} = (2\beta^2-1)(f/f_n)^2 \text{ neglecting all but the first two terms} \qquad (26)$$

From equation 24:

$$Y_{\text{approx.}} = 1-2\beta^2(f/f_n)^2+6\beta^4(f/f_n)^4 \ldots \qquad (27)$$

$$\xi_{\text{approx}} = \text{error} = 2\beta^2(f/f_n)^2 \text{ neglecting all but the first two terms} \qquad (26a)$$

$$\text{Ratio } \frac{\xi_{\text{approx.}}}{\xi_{\text{exact}}} = \frac{2\beta^2}{2\beta^2-1} \qquad (28)$$

The value of ΔT from equation 39 may be substituted into equation 24 to obtain Y directly in terms of ΔT:

$$Y = \frac{1}{\sqrt{1+(2\pi)^2(1.443\,\Delta T)^2 f^2}} = \frac{1}{\sqrt{1+(9.07 f\Delta T)^2}} \qquad (29)$$

For a maximum error of ξ per cent

$$\frac{100-\xi}{100} = \frac{1}{\sqrt{1+(9.07 f\Delta T)^2}} \qquad (30)$$

which solved for ξ:

$$\xi = 100\left(1-\frac{1}{\sqrt{1+(9.07 f\Delta T)^2}}\right) \text{per cent} \qquad (31)$$

$$= \frac{100(9.07 f\Delta T)^2}{1+(9.07\,\Delta T)^2+\sqrt{1+(9.07 f\Delta T)^2}} \qquad (32)$$

$$\approx (64.2 f\Delta T)^2 \text{ per cent for small errors where } (9.07 f\Delta T)^2 << 1 \qquad (33)$$

Solving equation 30 for f:

$$f = \frac{\sqrt{\epsilon(200-\xi)}}{9.07(100-\xi)\,\Delta T} \qquad (34)$$

This equation is plotted in Figure 6 with ξ as a parameter. The reciprocal, which is the period, is plotted in Figure 7. The range of ΔT plotted is from 0.001 second to

Figure 16. Comparison of the values of the component of relative damping reflected from the electrical side of a 3-milliampere recording milliammeter as obtained by calculation with those obtained from actual test by transient response methods

Figure 18. Curves showing the relationship between the minimum period and the peak-to-peak amplitude of a recorded signal for accurate response of a servo-actuated instrument in terms of the time required for full scale movement of the recording pen

1 second, which covers the range of most commercial instruments. The range of ΔT may be extended readily, however, as indicated by notes on the curves for values of ΔT which may fall outside the range plotted.

Approximations for Heavy Damping—Transient Response Curves

For large values of β, equation 16 may be written:

$$X = \epsilon^{-\frac{\omega_n t}{2\beta}} = \epsilon^{-\frac{t}{1.443\Delta T}} \tag{35}$$

since

$$\beta - \sqrt{\beta^2 - 1} = 1/2\beta + 1/8\beta^3 + 1/16\beta^4 + \ldots \tag{36}$$

This procedure is equivalent to neglecting the p^2 term in equation 12 and solving for X.

$2\beta/\omega_n$ is the time constant of the resultant damped-spring mechanical system. This may be replaced by the variable ΔT:

$$0.5 = \epsilon^{-(\omega_n/2\beta)\Delta T} \text{ by definition} \tag{37}$$

from which:

$$\Delta T = \frac{2\beta}{\omega_n} \ln 2 = \frac{1}{1.443}\left(\frac{2\beta}{\omega_n}\right) \tag{38}$$

$$\Delta T = \frac{\text{Time constant}}{1.443} \tag{39}$$

$$\Delta T = 0.2205\ \beta/f_n \tag{40}$$

D'Arsonval Movement

Equivalent Electrical Circuit to Represent Instrument

The equation of motion of the movement may be written:

$$J\frac{d^2\theta}{dt^2} + B\frac{d\theta}{dt} + T\theta = U_A i_A \tag{41}$$

and the equation of the coil circuit of the instrument is:

$$R_A i_A + U_A \frac{d\theta}{dt} = e(t) \tag{42}$$

in any consistent system of units. In the centimeter-gram-second electromagnetic system, each term in equation 41 represents a torque in dyne centimeters, and in equation 42 each term represents a voltage in abvolts. Let:

J = moment of inertia of instrument movement—grams (centimeter)^2/radian
B = damping coefficient—dyne centimeters seconds/radian
T = spring constant—dyne centimeters/radian
θ = deflection—radians
I_A = coil current—abamperes
t = time—seconds
R_A = coil resistance—abohms
$e(t)$ = voltage across coil terminals—abvolts
U_A = electromechanical coupling coefficient—dyne centimeters/abampere or abvolts/radian/seconds
$U_A = 2B'LNr_2$ where
B' = flux density in air gap of magnet—gauss
L = length of coil side—centimeters
N = number of turns in coil
r_2 = coil radius—centimeters

Changing the units in equation 41 from dyne centimeters to grams force at the end of the pointer, and changing the deflection from radians (θ) to per unit of full scale deflection (X) and the coil current to amperes:

$$\frac{kJ}{980\,r}\frac{d^2X}{dt^2} + \frac{kB}{980\,r}\frac{dX}{dt} + \frac{kT}{980\,r}X = \frac{U_A}{9{,}800\,r}i \tag{43}$$

Making similar changes in equation 42 as well as changing the units of the equation from abvolts to volts:

$$R_c i + \frac{U_A k}{10^8}\frac{dX}{dt} = E(t) \tag{44}$$

Equations 43 and 44 may be written:

$$M\frac{d^2X}{dt^2} + C\frac{dX}{dt} + KX = U_M i \tag{45}$$

$$R_c i + U_E \frac{dx}{dt} = E(t) \tag{46}$$

M = equivalent mass at end of pointer—gram (seconds)^2
C = equivalent damping coefficient at end of pointer—grams seconds
K = equivalent spring constant referred to end of pointer—grams/full scale deflection
r = pointer length—centimeters
k = full scale deflection—radians
X = deflection—per unit of full scale = θ/k
i = coil current—amperes
t = time—seconds
R_c = coil resistance—ohms
$E(t)$ = voltage across coil terminals—volts
U_M = electromechanical coefficient referred to mechanical side—grams force at end of pointer per ampere of coil current = $U_A/9{,}800\ r$
U_E = electromechanical coefficient referred to electrical side—volts per unit velocity of pointer = $U_A k\ 10^{-8}$

$$\frac{U_E}{U_M} = \frac{10^8}{98kr}$$

or

$$U_E = U_M kr 9.8\times10^{-8} = U_M l 9.8\times10^{-8} \tag{47}$$

where $l = kr$ = scale length in centimeters.

Equations 45 and 46 may be represented by the equivalent circuit shown in Figure 15. Mathematically the integral of the voltage v across the three parallel branches corresponds with the displacement. But since the current i_L also is proportional to the same integral, the current i_L may be considered analogous with the displacement by applying the conversion factors indicated in Figure 15. The impedance of the equivalent circuit between the terminals where $E(t)$ is applied is the same for all frequencies as that of the actual instrument. The equivalent circuit may be connected into any electrical network to replace the actual instrument and the effect on the electrical network will be the same. The current i will be the same as that taken by the actual instrument, and the current i_L will be proportional to the value the instrument records on its chart.

Determination of Instrument Constants by Test*

K may be determined by measuring the force at the end of the pointer for full scale deflection by means of a delicate spring balance.

U_M may be found by applying a constant known current to the movement and noting the deflection.

$$U_M = KX/i \text{ under these conditions} \tag{48}$$

For an ammeter, U_M may be computed directly from K and the full scale current rating of the instrument.

$$U_M = K/I_{fs} \text{ where } I_{fs} = \text{current for full scale deflection} \tag{49}$$

f_n and β may be found from a transient record making use of the curves of Figures 8 or 9. If the damping is less than 0.707, f_n and β may be obtained from a steady-state a-c frequency response curve. The response at the resonant frequency may be measured and β computed from equation 11. f_n may then be obtained from equation 10. If the phase can be measured readily, f_n may be determined by applying an a-c signal and changing the frequency until the swing of the pointer is 90 degrees out of phase with the applied signal. This latter method of

* Since this paper was written, a bridge method of measuring instrument parameters accurately has been presented by R. W. Gilbert and W. N. Goodwin, Jr.[13-14] The latter paper develops the theory upon which the method is based, and the former paper describes the equipment and technique of using it.

determining f_n is independent of the relative damping.

M may be obtained from f_n and K. This equation follows from equation 8.

$$M = K/(2\pi f_n)^2 \tag{50}$$

C may be obtained from f_n, M, and β. By combining equations 4 and 5:

$$C = C_c\beta = 4\pi f_n M\beta \tag{51}$$

U_E may be obtained from U_M.

$$U_E = 9.8lr\,U_M \times 10^{-8} = 9.8lU_M \times 10^{-8} \tag{47}$$

Damping Reflected From the Electrical Side

If the electrical resistance of the coil circuit (coil resistance plus the driving point resistance of the network into which the instrument is connected) is represented R_T, and if the motion of the movement is considered after a condition when $E(t)$ is suddenly made zero, equation 46 becomes:

$$R_T i + U_E\frac{dX}{dt} = 0 \tag{52}$$

Combining this equation with equation 45 to eliminate i

$$M\frac{d^2X}{dt^2} + \left(C + \frac{U_E U_M}{R_T}\right)\frac{dX}{dt} + KX = 0 \tag{53}$$

or in non-dimensional form

$$(p^2 + 2\beta\omega_n p + \omega_n^2)X = 0 \tag{12}$$

where ω_n is given by equation 4 and

$$\beta = \frac{C + U_E U_M/R_T}{C_c} = \beta_o + \frac{U_E U_M}{2R_T\sqrt{MK}} \tag{54}$$

$$\beta = \beta_o + \frac{\pi U_E U_M f_n}{R_T K} \tag{55}$$

Thus the relative damping consists of two components, β_o which is the relative damping inherent in the movement when the coil circuit is open, and β_1 which arises by virtue of current flowing in the coil when the coil circuit is closed.

$$\beta = \beta_o + \beta_1 \tag{56}$$

$$\beta_1 = \frac{\pi U_E U_M f_n}{R_T K} \tag{57}$$

Making use of equations 47 and 49

$$\beta_1 = \frac{9.8\pi lKf_n \times 10^{-8}}{I_{fs}^2 R_T} \tag{58}$$

β_1 = component of relative damping reflected from the electrical side

l = scale length—centimeters

K = force required at end of pointer to cause full scale deflection against the action of the restoring spring—grams

f_n = undamped natural frequency of the movement—cycles per second

I_{fs} = full scale current of instrument—amperes

R_T = resistance of instrument coil plus driving point resistance of the network which is connected across the coil terminals of the instrument—ohms

Equation 58 may be written

$$\beta_1 = F/R_T \tag{59}$$

where

$$F = \frac{9.8\pi lKf_n \times 10^{-8}}{I_{fs}^2} \tag{60}$$

Equation 59 is plotted in Figure 10 with β_1 as a parameter.

An experimental verification of equations 58 and 59 was made on two typical d-c milliammeters, the transient characteristics of which are shown in Figures 11 and 12. The relative damping was determined for each of the circuit conditions by Methods 1 and 2 described in the paper. The values of β_1 then were computed by equation 56. The resultant values then were plotted in Figures 16 and 17. These curves indicate also the relative degree of accuracy that can be expected in the determination of β by these methods.

Simplified Analysis of Servo-Actuated Recorders

For most servo-actuated recorders the proportional range of the servomechanism of the instrument corresponds to only a small fraction of the total scale range of the instrument. If a signal corresponding to more than this proportional range is applied, the pointer or pen will move across the chart at some maximum velocity, which depends upon the design of the instrument, until the proportional range is reached. For this type of instrument, the upper limit of frequency response is fixed by the maximum velocity of the recording pen. This maximum velocity is specified usually in terms of the time required for the pen to move from one end of the chart to the other under the influence of a signal large enough to give maximum pen velocity. The symbol T_{fs} is used to represent this quantity.

Since the fundamental limitation of response of such instruments arises from the fact that the pen velocity across the chart cannot be greater than some maximum value, the upper limit of frequency response depends upon the peak-to-peak amplitude of the signal as recorded on the chart. The symbol A is used to represent the peak-to-peak chart amplitude expressed as a fraction of the total chart width.

If the basic type of signal is taken as a sine wave of frequency f and period T, and the center of the chart is taken as a deflection reference:

$$X = (1/2)A \sin(2\pi ft) \tag{61}$$

and the maximum velocity on the chart will be

$$\left.\frac{dX}{dt}\right]_{max} = \pi fA = \frac{\pi A}{T} \tag{62}$$

This cannot be greater than $1/T_{fs}$ if the instrument pen is to be able to follow the changing signal.

$$1/T_{fs} > \pi fA = \pi A/T \tag{63}$$

$$A < 1/\pi fT_{fs} = (1/\pi)(T/T_{fs}) \tag{64}$$

or

$$T > \pi A/T_{fs} \tag{65}$$

If this condition is satisfied, the error in the record obtained at any point will not be greater than the proportional range of the servomechanism of the instrument. Expression 65 is plotted in Figure 18 with T_{fs} as a parameter.

The Locomotive Traction Generator Comes of Age

RICHARD LAMBORN
MEMBER AIEE

OVER 2,100,000 horsepower of Diesel-electric locomotives were produced in the United States during 1947. Other internal power locomotives, such as steam-turbine electric or gas-turbine electric and motor-generator locomotives, were built in very small quantities, but for our purposes may be added to the above total. All of these locomotives incorporate d-c traction generators of specialized design. Taken together, they account for the surprising figure of 70 per cent of the total d-c generator production of the entire United States for the year.

Compact, Lightweight Design

For a generator which is to be applied to locomotive service, small physical size (especially minimum over-all length) and light weight are items of paramount importance. These two requirements lead to a number of differences in design proportions as compared with the conventional generator built to spend its lifetime in a more or less fixed location. Traction generators are commonly designed with a large number of poles in relation to their capacity, since such machines tend to be relatively light in weight, and have short end windings and short commutators. Further shortening of the commutator by accepting higher than normal current density in the carbon brushes can be accomplished, provided the commutation factors and commutator surface conditions are made sufficiently favorable. Class *B* heat-proof types of insulation are used in all locomotive traction equipment because of the very considerable reduction in amount of active material made possible by the 120 degrees centigrade permissible continuous operating temperature rise.

All features of the mechanical design are made as simple and lightweight as torsional vibration conditions, buffing shock loads, and general over-all stiffness considerations will permit. Length required for purely mechanical functions is held to the minimum by building single-bearing machines having an antifriction bearing at the commutator end, and a bolting rabbet at the fan end of the armature spider to permit attachment to the driving flange of the prime mover. Such generators are often completely end-bell supported which makes a short, reasonably large diameter or "pancake" design much to be preferred to a longer, smaller diameter or "sausage" design, even though the latter might be slightly less expensive to manufacture.

Typical locomotive traction generator construction is illustrated in Figure 1, which shows the side view of a 2,000 horsepower Diesel-electric locomotive engine-generator set and by the section drawing, Figure 2, which shows the proportions of a somewhat smaller generator also built for end-bell mounting.

Concepts of Direct Current "Kva" and "Wrap-around"

When operating at rated load, prime movers such as the Diesel engine or the gas turbine are fundamentally constant torque output devices. Railroading, on the other hand, demands high-power outputs over a wide range of operating speed, which involve a widely variable torque demand. It is the flexibility and reliability with which electric drive can provide the required variation and multiplication in torque between the prime mover and the driving axles that account for the phenomenal growth of this branch of the electrical industry.

The required electrical size or D^2L (where D = diameter of the armature core and L = stacked height of the armature core) of a generator in stationary applications can usually be fairly accurately estimated from the horsepower and speed of the prime mover. However, the situation is somewhat more complicated in the case of generators applied in traction service. As a means of contributing their share to the torque range of the electric transmission system, traction generators are equipped with a means whereby their excitation is automatically regulated to make them deliver their full kilowatt output at high voltage and low current as well as at low voltage and high current, as indicated in Figure 3.

The specific range of volts and amperes over which such a machine is required to operate continuously becomes an important factor in determining its size. For instance, a generator driven by a Diesel engine delivering 1,500 horsepower net input will develop approximately 1,040 kw output, and in locomotive service this output may be required on a continuous basis anywhere within the range between 1,000 volts at 1,040 amperes to 500 volts at 2,080 amperes. In other words, the generator must be large enough to rate 1,000 volts and to also rate 2,080 amperes, although these do not occur simultaneously. In such a case, stating the capacity in terms of maximum rated volts times maximum rated amperes per 1,000 or $1{,}000 \times 2{,}080/1{,}000 = 2{,}080$ "kva" comes much closer to defining the size or D^2L required than the more conventional method of stating generator capacity in terms of kilowatts.

This same requirement may be expressed in a slightly different form by de-

Paper 48-116, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 2, 1948; made available for printing February 20, 1948.

RICHARD LAMBORN is a designing engineer of the transportation motor engineering division, General Electric Company, Erie, Pa.

The author wishes to thank his associates for assistance given him in the preparation of this paper.

Figure 1. Side view of 2,000-horsepower Diesel-electric locomotive engine-generator set

termining the ratio of maximum rated amperes to amperes at maximum rated volts or 2,080/1,040 = 2, and defining the generator size by saying it is a 1,500-horsepower input machine with a two to one continuous rating "wrap-around"; that is the range of currents over which the generator output must be extended or wrapped around the constant input volt-ampere hyperbola. The amount of wrap-around rating required in the generator of an internal powered locomotive depends chiefly on such factors as horsepower per ton on drivers, maximum locomotive speed at which full power is developed, traction motor characteristics, and motor control connections or combinations used. The relative effect of each of these factors can best be understood by working through a typical example with reference to Figure 4.

How to Provide Wheel Horsepower Over a Range of Locomotive Speed

Let us assume we wish to determine the amount of generator continuous rating wrap-around required on an 80-miles per hour Diesel-electric road-freight locomotive weighing 115 tons, having four axles, all motored, and equipped with a Diesel engine capable of developing 1,500 horsepower net for traction. To start with, general practice in freight locomotive service is to provide a maximum tractive effort for acceleration purposes equal to 30 per cent of the locomotive weight, which in our case would be $0.30 \times 115 \times 2000 = 69{,}000$ pounds. At the other end of the operating range, full available engine power should be transmitted to the rail up to at least 90 per cent of the maximum permissible speed, or $0.90 \times 80 = 72$ miles per hour. Assuming 93 per cent as a typical value of efficiency for the generator and 90 per cent efficiency for the traction motors, the tractive effort corresponding to this speed would be $0.93 \times 0.90 \times 1{,}500 \times 375/72 = 6{,}540$ pounds. From these two calculations we obtain the range in tractive effort or torque values which must be handled at full power by the electrical transmission equipment as $69{,}000/6{,}540 = 10.55$ to 1.

Since the torque developed by a motor is equal to some constant multiplied by flux and by armature current, it follows that the product of motor flux times motor current must be capable of variation over a 10.55 to 1 range to satisfy the requirements of our hypothetical locomotive application. On the average, a typical railway traction motor operating at rated horsepower would probably be limited to a 2.5 to 1 flux change by either heating, commutation, or flashover considerations. This means that the power delivered to our motors must be varied over a $10.55/2.5 = 4.22$ to 1 range of current values in order that they may be able to successfully handle full output over the required 10.55 to 1 range of torques.

A 1,500 horsepower generator capable of delivering its full kilowatt rating over a 4.22 to 1 range of currents would be a very large and heavy machine indeed. This condition can be greatly improved by providing a few relatively lightweight contactors to connect the traction motors in two parallel groups of two motors in series during acceleration and low speed operation, and to later reconnect them so as to place all four motors in parallel across the generator terminals for the higher operating speeds. This reduces the required generator current output range by a factor of two without in any way affecting the range in current flowing through the

Figure 2. Half section of typical locomotive traction generator designed for end-bell mounting

Figure 3 (right). Locomotive traction generator volt-ampere output characteristic

windings of each traction motor. The use of series-parallel motor connections has thus brought us down to a $4.22/2 = 2.11$ to 1 range of volts and amperes over which the generator must deliver full power.

Generator Heating

Let us now consider the range of volts and amperes over which the generator must rate continuously as contrasted to the 2.11 to 1 range over which we have determined that it must be able to handle full power.

Road freight locomotives are conventionally designed to have a continuous tractive effort rating of 15 to 16 per cent of their weight on powered axles. From the point of view of the series-excited traction motors, since their flux must decrease with decreasing load, the current required to develop 15 per cent adhesion must be more than half that required to develop 30 per cent adhesion. It follows that the continuous traction motor rating must occur in the series-parallel motor connection. Hence the maximum current that the generator must handle on a continuous basis will be required immediately following the transition from the series-parallel to the full-parallel motor combination. It would theoretically be exactly twice the current corresponding to the maximum rated voltage point of the machine. However, the maximum continuous rated load is often chosen as about 90 per cent of this value because the resultant saving in size and weight of generator is considered more worthwhile than whatever insulation life may be sacrificed from such over-temperatures as occur during the occasional periods of operation in the resulting small overload current zone. Thus we arrive at $0.9 \times 2 = 1.80$ to 1 range of volts and amperes as the continuous rating wrap-around required of the traction generator. To recapitulate, the ranges over which the electric equipment must handle full power on our hypothetical locomotive are:

1. 10.55 to 1 for traction motor torque.
2. 4.22 to 1 for traction motor current.
3. 2.11 to 1 for generator current.
4. 1.80 to 1 for continuous rated generator current.

Other Control Combinations Are Also Used

Frequently more than one feasible solution can be found to the problem of designing the transmission system for an internal-power locomotive, and the best solution will not necessarily be the one involving the smallest size generator. If using a single traction motor connection involves a big heavy generator, as in our example, the addition of series-parallel control to reduce the demand on the generator will effect a very appreciable saving in the cost and weight of the over-all transmission. But as smaller sizes of apparatus are approached in lower horsepower locomotives, a point will be found where the additional cost of a larger size generator required by the use of a single motor combination will be largely offset by savings in first cost and installation cost of those control items which are no longer required. Quite naturally, the choice will be biased in favor of the single motor connection alternative by consideration of such customer advantages as lower maintenance because of the simpler control equipment and improved service performance due to the locomotive being less "slippery" with only half as many motors in series under the high tractive effort conditions.

Although the generator applied in a single-motor connection transmission system always requires increased overload commutating ability, the chief pitfall in designing such a machine is more apt to be one of heating. Generally speaking, it is not adequate to design such a generator to have a continuous current rating corresponding to the combined continuous rated current of the traction motors in their operating combination. If this were done, it would be found that the generator could readily become badly overheated during operation at its maximum overload current while the traction motors were still within acceptable temperature limits. This to a large degree results from the fact that the load loss in the motor armature will be very low under such conditions because of its very low speed when exerting high torques, while the load loss in the generator armature will be very high because it may be running at or near its maximum speed. To be safe, a generator on a single motor combination locomotive should have a 15 or 20 per cent higher continuous ampere rating than the combined continuous ratings of the motors it supplies.

The optimum relative proportions of any specific locomotive transmission are likely to be distorted or compromised to some degree by the practical necessity of choosing from existing standard sizes of apparatus. Nevertheless, several general trends can be noticed in the data in Table I which presents a breakdown of the over-all transmission characteristics of a number of typical Diesel-electric locomotives. Item *B* represents our hypothetical locomotive which, except for an added complication in the control that was omitted from our example for the sake of simplicity, is identical with a currently very popular design of road freight locomotive. The other five items are all actual locomotives being manufactured today.

The first two locomotives listed serve to emphasize the fact that a generator used with a 2-to-1 series-parallel traction motor combination requires a 1.8-to-1 continuous rating "wrap-around." Using either an additional control connection on a 4-motor locomotive in which the motor fields are shunted in series-parallel before going into full parallel (Item *D*), or a 3-to-2 series-parallel combination on a 6-motor locomotive (Item *C*), serves to

Figure 5. Weight trend of locomotive traction generators

Figure 4. Steps in determining "wrap-around" requirement of traction generator for 115-ton 1,500-horsepower 80 miles per hour, Diesel-electric freight locomotive

Table I

Item	Locomotive Specifications, Including Horsepower for Traction; Weight on Drivers; Maximum Speed at Full Power; and Traction Motor Connections Used	Traction Motor Torque Range	Traction Motor Flux Range	Traction Motor Current Range	Generator Current Range	Continuous Rated General Current Range
A	600 hp; 70 tons; 50.5 mph utilization; 2S2P FS-1, 4P FS-1, 4P FS-2	11.20 to 1	2.69 to 1	4.16 to 1	2.08 to 1	1.82 to 1
B	1500 hp; 115 tons; 72 mph utilization; 2S2P FS-1, 4P FS-1, 4P FS-2	10.55 to 1	2.50 to 1	4.22 to 1	2.11 to 1	1.80 to 1
C	900 hp; 93 tons; 50.5 mph utilization; 3S2P FS-1, 2S3P FS-1, 2S3P FS-2	9.37 to 1	2.76 to 1	3.39 to 1	2.26 to 1	1.48 to 1
D	2000 hp; 110 tons; 67 mph utilization; 2S2P FS#1, 2S2P FS-2, 4P FS-1. 4P FS-2	6.45 to 1	1.95 to 1	3.30 to 1	1.65 to 1	1.49 to 1
E	2×210 hp; 80 tons; 16 mph utilization; 2 (2P) FS-1; 2 (2P) FS-2	6.26 to 1	2.29 to 1	2.73 to 1	2.73 to 1	1.90 to 1
F	2×400 hp; 51 tons; 50.5 mph utilization; 2 (2P) FS-1, 2 (2P) FS-2, 2 (2P) FS-3, 2 (2P) FS-4	6.56 to 1	2.94 to 1	2.23 to 1	2.23 to 1	1.59 to 1

Abbreviations designating motor connections are S = Series; P = Parallel; FS-1 = Full exciting field strength; FS-2 = Reduced field strength; FS-3 = Further reduced field strength; etc. For example 2S2P FS-1 indicates four motors operating on full field strength connected with two parallel groups of two motors each in series connected across the generator terminals.

reduce this required rating "wrap-around" to approximately 1.5-to-1. Translated into physical terms, this makes possible a reduction of approximately 15 per cent in the amount of active generator material required as compared with the straight 2-to-1 series-parallel type of control. No general rule for the required generator rating wrap-around on single motor combination locomotives (Items *E* and *F*) should be attempted, as it depends as much on the characteristics of the particular traction motor used as on any other factor.

A study of the tabulation as a whole serves to again point out the fact that for a locomotive of given weight and fixed maximum full-power speed, the required traction motor-torque range is inversely proportional to the prime mover horsepower. From here it is but a simple step to the realization that if weight and utilization speed are established, increasing the horsepower will not involve a proportionate increase in the size of the electrical transmission equipment.

Switcher Generators Differ From Road Locomotive Generators

Thus far, the entire discussion regarding ratings has referred to what is commonly classed as road-locomotive type of service which implies that all the equipment has been designed to permit sustained full power operation. While this is by far the more glamorous field for the design and application engineer, there are two other distinct classes of service for which Diesel-electric locomotives are built in large quantities. One of these is railroad yard switching service. Because of the low-load factor in this type of operation occasioned by the frequent off-and-on nature of the power requirements and many light-load movements, it is permissible to design such an electrical transmission with somewhat reduced ratings and to rely upon the reduced load factor and low rms effective current to prevent overheating of the equipment.

Locomotives designed for use by industrial plants constitute the third major classification. Many industrial railroad systems have such a small total length of track that it is almost impossible to think of service on them in terms of continuous rating or continuous operation. In fact more than 600 such locomotives of one particular design have been operating successfully for years with generators so small in size that they cannot be operated continuously at any point on their full horsepower volt-ampere characteristic curve without exceeding AIEE Class *B* permissible temperature rises. Designing for such special applications should of course be based on actual service experience whenever possible rather than on any generalized rules such as here developed for the road locomotive type of service.

Various Means Employed to Produce Hyperbolic Volt-Ampere Curve

Another factor which influences the size and weight of a generator to some extent is the particular means employed to obtain the automatic regulation of its output over the required range of current and voltage. There are at least five different schemes in general use, ranging from the simplicity of a self-excited generator which depends entirely on the stalling characteristics of a diesel engine for its ability to produce a wrap-around type of output curve, to the amplidyne exciter which, in conjunction with the electro-hydraulic governor, (1) prevents engine overloading or stalling at all engine speeds and has the further ability of adding predetermined voltage and current limit cut-offs (2) to the generator hyperbolic volt-ampere characteristic. The self-excited generator with stalling control is used only on small-capacity power plants such as those designed for industrial service where minimum first cost is an important objective.

Second in order of increasing complexity is the scheme using a controlled saturation type of differential field exciter. It has been successfully applied to a large number of switching locomotives and does an excellent job of matching the generator's demand to the engine's output ability under one specific set of design conditions. However, it lacks ability to correct for variations in torque demand of the generator such as those caused by higher or lower than normal exciting field temperatures or for variations in torque ability of the Diesel engine due to fouled injectors, change in altitude, or normal wear and tear. The third scheme is an outgrowth of the second and, since it overcomes the difficulties just enumerated, it meets the essential requirements of an excitation system suitable for road type of service. It is characterized by the addition of an engine governor servo-operated rheostat in the battery field circuit of the controlled-saturation exciter whereby the excitation of the main generator is regulated so that its output is made to match the capabilities of the Diesel engine. Neither of these systems has an inherent generator overload current limit feature. The partial power volt-ampere characteristics tend to be undesirably flat for optimum locomotive accelerating performance, and the excitation tends to be unnecessarily high at the lighter loads beyond the point where the volt-ampere curve has departed from the constant horsepower portion of the characteristic.

The fourth scheme uses no exciter, but requires three exciting field windings in the generator; namely, self, separate, and differential, with a governor servo-operated rheostat in the battery-excited separate field winding circuit. Naturally, the rheostat and its servo-mechanism must be much larger when working directly on the main generator field than when working on the field of an exciter. In such a generator the field structure must be relatively deep to accommodate the greater gross number of ampere turns resulting from the use of an opposing series differential winding, and to allow

for the extra amount of insulation needed when using a multiplicity of field windings.

The fifth scheme based on the use of the amplidyne type of exciter requires the smallest capacity of servo-operated rheostat, produces the most desirably shaped family of partial power characteristic curves, and by providing definite overload and over-excitation protection, permits the designer to use the minimum of material in the construction of the generator stator parts.

Other Functions Performed by Traction Generators

In addition to the primary function of providing power for propelling the locomotive, the traction generator usually has other secondary functions. On locomotives using Diesel engines as their prime movers, it is almost universal practice to "motor" the traction generator from a storage battery in order to crank the engine and get it started. In the case of the gas-turbine type of power plant, supplying power to the main generator promises to be the preferred way of bringing the turbine-compressor unit up to a self-sustaining speed as well as for turning it over slowly during the cool-down period required prior to the actual shutting down of a unit that has been up to operating temperature. Similarly on the motor-generator set type of trolley locomotive, motoring the traction generator from some auxiliary source of d-c power is the preferred method of getting the synchronous motor above half speed where the single phase power can effectively accelerate and pull it into step. A separate series winding is built into the generator for this starting duty on small and medium sized machines, but in the largest size units the series winding is sometimes omitted and control equipment added to permit the use of the machine's regular separate excitation winding for the motoring operation.

A more recent function, which at the present time is required only on locomotives used in road freight or road passenger service, is that of providing excitation for the traction motors when they are operating in their braking connection. Electric braking is accomplished by connecting the traction motor armatures to a set of forced air-cooled grids, and regulating their excitation to suit the braking requirements of the train. The separate excitation power for these motor series fields is required at a relatively low voltage, and is obtained from the traction generator while being driven at the minimum operating, or idling, speed of the prime mover. This requirement seldom involves any heating problem, but may offer one in stability of operation, as proper equalization of the load between similar units operating in multiple from a single head-end control station is a universal requirement. Arranging the traction-motor field excitation circuit to include the generator cranking winding so that it will act as a differential series exciting winding is one means of at least improving the equality of load between units.

Traction generators have at times been used to furnish at least a portion of the auxiliary power requirements of the locomotive. In certain switcher locomotives they have been arranged to charge the storage battery whenever the engine was idling, with the traction motors consequently disconnected from the generator circuit. In other cases, motor driven air compressors or blowers have been operated from the variable voltage delivered by the generator while it was supplying power for traction. Such practices, however, have never been and probably never will be universally accepted by the industry.

Striking Progress in Design Is Continuing

The first commercial Diesel-electric locomotive in the United States was built in 1925, but as of that date the design proportions of the traction generators had not departed very greatly from those used in industrial practice. During the following ten-year period a three-to-one reduction in weight per kilovolt-ampere of continuous rating was accomplished as indicated by the data of Figure 5. This enormous technological advance was due in part to the engine builders' increase in the horsepower output and speed of their prime movers, but to a much greater extent, it was the result of the efforts of the electrical industry in developing the highly specialized designs of generators according to the principles that we have been discussing. Although the designs of locomotive generators were frozen during World War II, the curve of progress is seen to have flattened out to a great extent even before the war period. Since the war the curve has taken a new dip toward still lower weight per kilovolt-ampere. This second, though materially smaller, advance is again due in part to the availability of higher speed, higher horsepower, prime movers and in part to the electrical industry's further improvements in insulations, excitation systems, and motor control techniques for road locomotive application.

Conclusion

In the 60-year old electric-traction industry, the 22-year old locomotive traction generator is a comparative youngster, but on reaching maturity it has assumed a role of major importance. Business in these generators in 1948 promises to exceed that of 1947, with a probable production of 2,500,000 horsepower. There has been striking progress in design through the years and the future holds promise of further interesting developments with a continuing trend toward higher speed, higher horsepower, and still more output per pound or per cubic foot.

Formation of Insulating Oxide Films on Electrical Steel

P. L. SCHMIDT
ASSOCIATE AIEE

General

IN order to reduce eddy current loss to a minimum, the magnetic cores of electric machines designed to operate on alternating current are assembled in laminated form from silicon steel punchings which are insulated from each other by the application of special coatings to the surfaces of the sheets or laminations. Various types of varnishes and films produced by a chemical reaction are being used as insulating coatings but most of these fail to meet one or more of the requirements of a satisfactory interlaminar surface treatment. The important requirements of an insulating film are low cost, ease of application, small decrease in space factor in the core, high electrical resistance, high corrosion resistance, and good paint adherence.

Insulating films which fulfill these requirements can be produced by heat treating punchings to form an oxide on the surface of the steel. The problem is to obtain consistently a tightly adherent, thin oxide having a high electrical resistance. Obviously, the formation of ferric oxide, common red rust, must be avoided because it is thick and loose, thereby resulting in an undesirable decrease in space factor and presenting handling problems.

It has been found that thin, tenaceous, highly resistant films of magnetic oxide can be formed by heat treating punchings in a batch process at 400 to 550 degrees centigrade in a steam atmosphere containing not more than 0.5 per cent free oxygen. On one per cent silicon steel this treatment produces a film which has a median interlaminar resistance of at least 20 ohms centimeters squared per lamination and which decreases the space factor less than one per cent. Interlaminar resistance measurements are usually made on rotor punchings about four inches in diameter in accordance with the procedure outlined elsewhere.[1]

The batch-type process which has been highly successful consists of placing the charge in a bell-type or car-type batch furnace and covering it with a sand sealed metal inner cover. During the oxidation part of the cycle, steam is introduced into the inner cover and allowed to diffuse out through the sand seal. A more practical production method may be carried out in a conventional continuous furnace at temperatures between 400 and 550 degrees centigrade provided that steam is supplied to and free oxygen excluded from the oxidizing zone of the furnace.

When attempts were made to oxidize laminations in conjunction with a strain annealing process in a continuous-type furnace, a procedure which is very desirable commercially, it was found that films with satisfactory physical properties could be obtained using an atmosphere composed of CO, CO_2, H_2, H_2O, and N_2. However, these films were found to have an interlaminar resistance approximately 1 per cent of that obtained by oxidation in a steam atmosphere at 500 degrees centigrade.

The following experimental work was undertaken to determine the difference between oxide films having substantially the same bluish-gray characteristic color and the same desirable physical characteristics, such as thinness, toughness, and tenacity, but high electrical resistance on one hand and low resistivity on the other.

Paper 48-120, recommended by the AIEE rotating machinery and transformer committees and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico D. F., Mexico, June 21–25, 1948. Manuscript submitted February 2, 1948; made available for printing March 4, 1948.

P. L. SCHMIDT is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Background

A continuous process set up for experimentally strain annealing and oxidizing stator punchings for small motors was carried out in a pusher-type continuous furnace consisting of a heating zone, controlled cooling zone, and a fast cooling zone. Combusted gas generators which may be adjusted to give various proportions of CO, CO_2, H_2, H_2O, and N_2, supply a controlled atmosphere to this furnace, and, by varying the amounts of the reducing and oxidizing components of the gas at a given temperature, either a reducing atmosphere or an oxidizing atmosphere may be supplied to the furnace.

It is claimed to be theoretically possible[2] to obtain a combusted gas mixture which is reducing at annealing temperatures of approximately 725 degrees centigrade and oxidizing at lower temperatures. However, the range of component gases over which this may be possible is very small so that variations in the composition of the gas supply or in the temperature of the cooling water of the combusted gas generator causes large variations in the oxide film produced. The first method of annealing and oxidizing in the continuous furnace was carried out in an attempt to obtain this type of atmosphere. It was believed that the punchings would be protected from high temperature oxidation which causes undesirable sticking and which is difficult to control, and that an oxide film would be produced on the punchings when they reached the controlled cooling zone without causing undue sticking or too great thickness of film.

Furnace temperatures from 600 to 725 degrees centigrade, combusted gas atmospheres ranging from the richest mixture possible with the available equipment to very lean atmospheres with excess oxygen, and dew points ranging from 10 to nearly 100 degrees centigrade were tried.

Figure 1. X-ray diffraction pattern of an oxide film of low-electrical resistance

Summarizing the results of these trials, it appeared that:

1. High dew points in the high temperature zone with either rich or lean combusted gas caused undesirable sticking.

2. Lean, dry combusted gas gave a film which was too thick, usually flaked off, and had very low interlaminar resistance.

3. Rich, dry combusted gas produced films of very low resistance partly because they were not much thicker than temper films.

4. On rare occasions a batch of punchings would be produced which had a tenaceous, thin, blue oxide film which gave high interlaminar resistance.

In regard to the fourth point just mentioned, poor results were also obtained under seemingly exact conditions of temperature and atmosphere. This indicated that although the proper conditions in the furnace may be possible, it is very unlikely to consistently achieve these conditions in production. It was found that a great deal of variation existed in the punchings annealed in this manner.

It was then decided to supply a rich, dry combusted gas atmosphere to the high-temperature zone of the furnace and to add water vapor into the controlled cooling zone. By admitting the combusted gas atmosphere into the high-temperature zone only and by closing the gas exhaust port at the charging end of the furnace, it was believed that the large flow of gas toward the exit end of the furnace would prevent the back diffusion of water vapor into the high-temperature zone. The purpose of this method was to prevent oxidation of the laminations entirely while at high temperature, and to promote oxidation in the controlled cooling zone after they had cooled to temperatures where the oxidation process could be better controlled.

It has been found that the product obtained by this method was fairly consistent so far as physical appearance was concerned, that the films had a grayish appearance and a median resistance of approximately 0.2 ohm centimeters squared per lamination which is slightly better than that obtained by the previous method.

Although the combusted gas and steam process produces oxide films which have fairly satisfactory and consistent physical characteristics and which have sufficiently high interlaminar resistance for punchings which are 3/4 inch wide behind the teeth, two problems still existed. The problems were:

1. What is the fundamental chemical or physical difference between these low resistivity oxide films which are produced in conjunction with the strain anneal and the high resistivity films which can be produced in steam between 400 and 550 degrees centigrade, both of which have substantially the same physical appearance?

2. Can a process be set up for continuous oxidizing and annealing such that a thin, tightly adherent oxide film of high electrical resistance will be obtained?

Investigation of High-Resistance and Low-Resistance Oxide Films

A great deal of development work on the difference between the high-and-low-resistance films has been done and a satisfactory solution to the problem has been obtained. In order to obtain the information concerning the difference between high-resistance films and low-resistance films, a comparative study of the two types of oxides was made by X-ray diffraction analysis. The first method used was to obtain an X-ray diffraction pattern of the coatings by reflecting X rays from the coating on the steel. A diffraction pattern from the bare steel was then subtracted from the pattern obtained from the steel and film together. Using this method, a sample of one per cent silicon steel which was annealed at 725 degrees centigrade and oxidized at 500 degrees centigrade in a lean combusted gas atmosphere and also a sample of one per cent silicon steel which was steam oxidized at approximately 500 degrees centigrade were examined. This method of analysis indicated that the oxide formed in combusted gas at 725 degrees centigrade and the oxide film formed at 500 degrees centigrade in a steam atmosphere were essentially Fe_3O_4 and contained a slight amount of Fe_2O_3.

It happened that the film which was formed at the higher temperature could be stripped off rather easily by bending the sample, so it was decided to make an X-ray study of the oxide powder itself. The results of this test showed that the oxide film contained a large amount of metallic iron. This showed that the iron lines which were present in the first analysis were not only due to the base metal, but were also caused by metallic iron in the film itself. This was the first clue to a possible difference between the high-resistance and low-resistance oxide films.

This experiment was now repeated with samples from the annealing and oxidizing process using combusted gas and water vapor as described before, and equivalent samples oxidized in a steam atmosphere at 500 degrees centigrade. It was found that the film formed in the continuous furnace contained a large amount of iron, and the low-temperature oxide film formed in a steam atmosphere contained very little metallic iron. Figure 1 shows an X-ray pattern of the oxide film removed from a typical punching which was annealed and oxidized in the continuous process. Figure 2 shows an X-ray diffraction pattern of the oxide produced in the steam atmosphere at 500 degrees centigrade. It will be noted that in the case of the former oxide, the Fe lines are very prominent and the Fe_3O_4 lines are in comparison very weak. The reverse is evident in the figure showing the X-ray diffraction patterns of the high-resistance film; namely, the Fe_3O_4 lines are prominent and the Fe lines are faint.

The distribution of interlaminar resistance corresponding to the films of Figures 1 and 2 are plotted as curve *B* and curve *A* respectively in Figure 3. Samples

Figure 2. X-ray diffraction pattern of an oxide film of high-electrical resistance

Figure 3. Distribution of resistance values

A—Tests made of 12-inch squares oxidized in a steam atmosphere at 500 degrees centigrade for four hours

B—Ten-inch square stator punchings, 3/4 inch wide behind teeth, annealed at 725 degrees centigrade in rich combusted gas, steam added in cooling zone to increase moisture to 15 per cent

for these tests were taken from the same heats as those from which the samples were taken for the X-ray diffraction analyses shown in Figures 1 and 2. Curve *B* has a median of 0.11 ohm centimeters squared per lamination and curve *A* has a median of 50 ohms centimeters squared per lamination which may have been as low as 25 ohms centimeters squared per lamination had the tests been made on punchings instead of squares.

A semiquantitative X-ray analysis of these films was then made. In order to do this, X-ray patterns of pure iron powder mixed with various amounts of Fe_2O_3 were obtained. Using these three patterns as standards for the different percentages of iron, the amount of iron in the high-and-low-resistance films could be estimated by the techniques employed in X-ray diffraction analysis work. It was found that the low-resistance films contained approximately 50 per cent metallic iron and the high-resistance films contained approximately 10 per cent free iron.

The reason for the presence of metallic iron in the low-resistance oxide films was found in the literature[3] on the subject. It is pointed out that under controlled oxidizing conditions above 570 degrees centigrade, iron oxidizes to form only ferrous oxide (FeO). When this oxide is subsequently cooled below 570 degrees centigrade, it becomes unstable and decomposes to form ferro-ferrosic oxide (Fe_3O_4) and metallic Fe. Below 570 degrees centigrade, FeO does not form to any great extent and thus films which are formed below this temperature do not contain an appreciable amount of metallic iron.

Method of Obtaining High-Resistance Oxides in a Continuous Process

The results of the X-ray diffraction analyses indicate that if it is desired to anneal laminations at temperatures of approximately 725 degrees centigrade and then to oxidize in conjunction with this annealing procedure, it is necessary to keep the punchings bright during the annealing cycle and during the time while they are cooled to a temperature below 570 degrees centigrade. The bright punchings can then be oxidized in a controlled atmosphere without the danger of forming FeO.

It is almost impossible to carry out this procedure in a conventional type of continuous furnace by introducing combusted gas into the annealing zone and steam into the latter part of the controlled cooling zone. There is enough back diffusion of steam even against a positive flow of gas from the charging end of the furnace to the exit, so that the punchings are oxidized above 570 degrees centigrade and FeO is formed.

A type of furnace such as that shown in Figure 4 would be necessary in order to produce the satisfactory oxide in conjunction with a continuous annealing process. This furnace consists of an annealing zone and an oxidizing zone separated by a gas-tight transfer chamber. A reducing atmosphere is maintained in the annealing zone and the transfer chamber, and an oxidizing atmosphere such as steam is supplied to the oxidizing zone. The punchings are cooled to a temperature below 570 degrees centigrade before entering the oxidizing chamber of the furnace, and the transfer zone is so arranged that it will serve to keep the oxidizing atmosphere from contaminating the reducing atmosphere in the annealing zone.

Figure 4. Continuous annealing and oxidizing furnace

Zone 1—Purging chamber, reducing atmosphere

Zone 2—Annealing zone, 700–850 degrees centigrade, reducing atmosphere

Zone 3—Controlled cooling from annealing to oxidizing temperature, reducing atmosphere

Zone 4—Transfer zone, reducing atmosphere

Zone 5—Oxidizing zone, 400–550 degrees centigrade, steam atmosphere

Zone 6—Cooling from oxidizing temperature to slightly above 100 degrees centigrade, steam atmosphere

Zone 7—Exit chamber, inert atmosphere

Conclusions

The results of this investigation show:

1. Low resistivity of oxide films is caused by conducting particles of metallic iron distributed throughout the film.

2. The oxide film which is formed in the conventional continuous annealing and oxidizing process contains a large amount of metallic iron caused by the oxidation occurring above 570 degrees centigrade. At this temperature FeO is formed which later decomposes into Fe_3O_4 and Fe.

3. In order to obtain a film which is not contaminated with metallic iron, it is necessary to carry out the oxidation below 570 degrees centigrade. If annealing as well as oxidation is desired, the punchings must remain bright during the annealing cycle and while they are cooling to the oxidizing temperature.

The Increasing Uses for Electricity in Land Transportation

CHARLES KERR, Jr.
MEMBER AIEE

COMMERCIAL land transportation fundamentally falls into two major classifications, the transportation of passengers in urban communities and the intercity transportation of both passengers and freight. In the United States alone, this industry operates 175,000,000 installed horsepower for the movement of its traffic. Potentially, no other single industry offers the electrical manufacturers such a broad opportunity for expansion in the use of electric equipment.

Often fears have been expressed that new prime movers like the internal combustion engine, the steam turbine and, ultimately, the gas turbine will minimize the importance of electrical equipment to this industry. Actually, with one major exception, the exact opposite has been the case. Land transportation generally is becoming increasingly more dependent upon electricity, not only in motive power, but in those allied operations which are essential to the efficient and expeditious movement of traffic.

Figure 1 shows the extent to which electric equipment has been adopted by this industry, together with the changes which have occurred in a 20 year period. Of even greater significance is the rapid expansion during the past few years, illustrated by Figure 2. While total figures for 1947 are yet unavailable, sufficient information exists to indicate that motive power purchases alone in that year will equal all purchases during 1946. The present rate of expansion exceeds all previous experience.

Urban Transportation

Public transportation in urban centers is an essential service with problems of ever increasing perplexity. It can be supplied by the motor bus, the trolley coach, the street car or rapid transit train, often most economically by a combination of these vehicles. Excluding the motor bus, all are electrically operated. However, the fact cannot be overlooked that the motor bus has made its place in urban transit, often threatening the supremacy of the electrically operated vehicle. Looking to the future, the use of elecric vehicles should be given added impetus by the rising price of liquid fuels contrasted to a more constant price for electric power.

The Trolley Coach

The electrically propelled trolley coach is becoming very popular. It provides maneuverability in city traffic, the inherent advantages of electric propulsion, and satisfies the insatiable desire of the peoples of the world to ride on rubber tires. It will give a faster and a smoother ride than the motor bus. Wherever once installed, it has met with an instant public acclaim. For small and medium size cities, and for feeder lines in metropolitan centers, the trolley coach should have a promising future. Its rapid growth is rather significant of a return in popularity of the electrically propelled vehicle to the field of public transportation. The modern coach is not only economical to operate, but affords a fast and pleasant ride for the public upon whose patronage its ultimate success depends. As of January 1, 1948, over 6,600 trolley coaches were in service or on order.

The Street Car

The street car represents the one conspicuous application inland transportation where electricity has decreased in usage. Two principal causes have contributed to this downward trend. The motor bus, traveling a right-of-way furnished by the taxpayers, has the advantage of a very low investment, and on lines of light traffic, may operate at a low cost. The street railway industry also was slow to meet this competition with improved equipment.

To stop this trend, the operating companies and the equipment manufacturers finally combined their efforts to produce a standard surface car with excellent riding qualities that could be produced at a reasonable price. This vehicle has restored the street car to public favor by furnishing a smoother, faster and quieter ride. It has demonstrated that the street car can definitely survive for heavy surface transportation if it will keep pace with technical development.

Rapid Transit Systems

For the mass movement of passenger traffic, the rapid transit systems of large metropolitan centers have no parallel. Present four track lines can carry upwards of 200,000 passengers per hour, and the contemplated six track line for New York City should exceed 300,000 passengers per hour where over 200 trains of ten cars each may pass a given point per hour. While these systems are truly marvels of engineering, they are equally marvels of operating technique. Nowhere is reliability and safety of electric equipment required to an equal degree. Delays of a few minutes can cause a major disruption to the life of a community.

These systems represent huge investments. Thus, the major engineering considerations in their construction are directed toward moving the maximum number of people with safety and efficiency. Without electric operation, they,

Figure 2. Annual purchases of electric equipment by the land transportation industry

and the metropolitan centers which they serve, would be an impossiblity.

Trends in Urban Transportation Equipment

Practically all city transit services operate from 600-volt d-c power. This system has proved so satisfactory that its supremacy is generally unchallenged. For the supply of this power, the mercury arc rectifier has reached universal acceptance.

But, during recent years, the apparatus used for propulsion purposes has undergone a complete transition. These changes have been dominated by a need for greater standardization to reduce first and operating costs, and by a realization that the public continually demands faster service and a better ride.

A convenient example might be taken to illustrate the trend towards standardization. Twenty years ago, the Westinghouse Company manufactured many different types of 600-volt traction motors for city transit vehicles with innumerable minor modifications of these major types to meet the particular whims of its customers. Today, three motors cover its production, one each for trolley coaches surface cars and rapid transit cars.

Accelerating rates have continually been raised until some exceed 4.0 miles per hour per second. These high rates, available only with electric propulsion, are imperative to secure fast service with frequent stops. It has been found also that fast starts are perfectly compatible with passenger comfort if the proper system of control is provided. Fast braking is equally important. All modern transit equipment has adopted electric braking, utilizing the traction motors as generators to produce retardation. By so doing, fast rates are secured, brake maintenance is reduced, and energy recovered to heat the coaches in cold weather.

Besides a faster ride, today's passenger demands a more comfortable ride. To this end, the control equipment has been developed for smooth operation. Spring supported motors and rubber insert wheels reduce noise. Forced draft ventilation is being adopted, and better lighting installed. In addition to these electrical features, the trucks and car bodies are receiving careful attention. To summarize, all modern city transit developments are being directed towards a faster and smoother ride.

Economical Use of Different Vehicles

The proper place for each type of vehicle in public transportation is governed by the volume of traffic to be carried. Figure 4 shows their respective maximum capacities in a single lane. For light density traffic, the bus can readily supply the necessary functions of public transportation, but whenever the volume reaches concentrations of appreciable magnitude, other types of transport must be utilized. This chart shows primarily the maximum capacity of these vehicles, not necessarily the most economical field for each.

Figure 5 supplies an approximate chart of their respective economical zones of application. The motor bus, due to its low initial cost and absence of large auxiliary investment, meets the needs of light traffic with ecomony. In the next zone, the electrically propelled trolley coach comes into the ascendency where sufficiently dense traffic justifies the overhead trolley investment but is insufficient to warrant the laying of track. From 4,000 to 13,500 passengers per hour, the modern surface car generally affords the most economical transportation. Whenever the density exceeds 13,500 passengers per hour, some form of rapid transit becomes essential to cope with the traffic.

This chart applies to average conditions existing throughout the United States. Among the several cities of that country or among cities of other countries, local conditions may change the exact points of demarkation between the economical zones as they are shown. However, these charts bring out one very significant fact—all large urban centers are absolutely dependent upon electrical equipment to furnish public transportation with economy.

City transit problems have not always received the logical consideration which they deserve. Fortunately, there is a growing appreciation of their importance, and especially, a realization of the rightful place for the various types of transport. These are extremely healthy conditions, and from this better understand-

ing of the problems involved, there will certainly come a better evaluation of the importance of electricity in city transit.

Suburban Operation

Suburban operations of the main line railroads are a part of the transportation service of many large cities, but are not performed by the commonly accepted local transit properties. Approximately 50 per cent of all commuting passengers in the United States are handled by electrically operated multiple unit trains.

Where congested traffic exists, the so-called multiple unit train affords a delux type of transportation for urban communities. It also removes many complicated operating problems. Where the traffic does not reach dense proportions, locomotive hauled trains furnish this service.

Recently, Diesel-electric locomotives have been introduced and some roads are contemplating a combination trolley-diesel-electric locomotive. Electric drive, whether applied to a locomotive or car, gives the rapid acceleration so essential to fast schedules.

Main Line Railroads

The uses for electricity on the main line railroads are not confined to locomotives alone, but extend to the many allied services. While motive power represents by far the largest power demands, many of the other uses for electricity are extremely interesting and represent rapidly expanding operations.

Safe high-speed train operation would be impossible without signal systems, all electrically operated. These systems have reached their highest state of perfection where a continuous indication is provided in the cab of the locomotive, making visibility of the signals entirely independent of outside weather conditions.

For communication purposes, the major railroad systems maintain huge telephone and telegraph plants. But communication between fixed wayside points alone is proving to be no longer adequate for modern operation. Today, voice communication to and from moving trains is being installed, communication between moving trains, and from head to rear end of moving trains. For this type of communication, either radio or the inductive system is used.

Communication is now going even further with passenger trains carrying telephones for the use of the traveling public. Before long, you will be just as accessible to telephone service on a train as in your own home.

There are additional applications for electric machinery in wayside operations and maintenance shops too innumerable to review. One survey indicates that 150,000 motors and generators are used for such purposes by the railroads.

The electrical equipment for modern passenger cars injects many different problems in design. The power supply for most cars is provided by an axle driven generator which must supply full load over a range in speed from 25 to 100 miles per hour with almost perfect voltage regulation. This same generator operates under the worst possible conditions and may travel from road to road, so that reliability is essential. With air conditioning and other accommodations provided by modern cars, car generating plants range from 20 to 30 kilowatts each. The peak load of a 15-car train may be 300 to 400 kilowatts, or 10 to 15 per cent of the locomotive capacity.

The many auxiliary services maintained by the railroads often are overshadowed by the tremendous concentration of power in the locomotives themselves. Those mentioned here are but a few of many, any one of which is well worthy of a separate paper. Modern transportation embraces uses for practically every type of electrical equipment, both in the generation as well as use of electric power.

Motive Power

Six types of locomotives will be available to move the main line traffic of the future, reciprocating steam, geared turbine, turbine-electric, diesel, gas turbine and electric. Four of these depend upon electric transmissions for traction purposes, and it is these four which are now definitely in the accendency. If this trend should continue, all main line roads eventually may be operated by straight electrification or by electric locomotives carrying their own power plants.

Electrification

Electrification is the best means yet devised for the operation of a railroad. It has only one serious limitation, a relatively large initial investment. In spite of this handicap, more railroads are adopting or expanding its use, especially outside of the United States.

Certain conceptions regarding electrification are changing, all for the good. For many years, electrical engineers fought the so-called "Battle of the Systems," or alternating versus direct current. Today, it is appreciated that either system can solve satisfactorily any electrification problem, and the final choice is dictated by local conditions. If a generalization is possible, alternating current is usually preferable where heavy concentration of loads is encountered, while direct current proves more economical where many trains are operated with smaller individual peak demands, producing a more evenly distributed system load.

It is also better appreciated that the cost and the availability of fuels are very controlling factors in the over-all economy of electrification. The prices of oil and coal are increasing while the price of electric power remains essentially stationary. (Figure 6). This relationship in the relative prices of fuel and power may exert a profound influence on the future fortunes of electrification.

The United States is blessed with a substantial supply of fuel which can be produced at a reasonable price, consequently, railroad electrification generally has been confined to those regions where traffic density dictated its use or where operating problems were encountered which could not be solved otherwise. In many other countries where fuel is not equally abundant at a low price, water power is being developed as a major source of energy, making railroad electrification an economic necessity.

As the nations of the world become more highly industrialized, rail traffic is increasing in density so that existing methods can scarcely cope with its volume. Electrification will increase the traffic capacity of these railroads at a lower first and operating cost than that involved in laying additional track. This is particularly true where the road bed is laid with light rail, the grades are severe or narrow gauge is used.

A reduction in the capital investment required for electrification would expand its application. Greater standardization of all component parts offers the best medium for accomplishing this purpose. As an example of the possibilities along this line, a complete series of locomotives from 1,875 to 7,500 horsepower has recently been proposed, constructed from identical basic components. The same four wheel trucks and the same motor would be used on all locomotives. Only the motor gearing would be changed for passenger, freight or switching service. Many control items would be identical, differing largely in quantity used according to the locomotive capacity. A series of this kind with the proper motor is equally applicable to 3,000-volt d-c systems or 12,000-volt a-c systems of electrification.

A modern design of a 7,500 horsepower locomotive, Figure 7, is illustrative of electric motive power at its best. In a single unit, greater capacity is developed than 3- or 4-unit diesels provide. All weight is carried on 16 driving axles, permitting large starting and running drawbar pull, yet imposing low axle loads on the track structure. Mechanically, it is satisfactory for speeds of 100 miles per hour or over. Weights and clearances are acceptable to any road which can handle a standard 85-foot passenger car.

Figure 6. Trend of electric power and fuel prices for railroad service

Figure 7. Electric locomotive of 7,500 continuous horsepower

It incorporates practically every desirable feature demanded by modern motive power.

Electrification will continue to be used by the railroads of the world to a greater extent. Its rate of expansion will be determined largely by the ability of the manufacturers to reduce its first cost, by the need of the railroads to increase their traffic capacity, and by the relative price of electrical energy compared to the availability and price of other fuels.

The Diesel Electric Locomotive

Wherever Diesel electric locomotives are discussed, these advantages are always cited:

1. Constant rail horsepower over the normal operating range of the locomotive, providing a versatility unobtainable from the reciprocating steam locomotive.
2. A multiplicity of lightly loaded driving axles with all or most of the locomotive weight utilized for adhesive purposes.
3. Exceptionally high starting and running draw bar pull.
4. A decided increase in train tonnage.
5. Ease in the handling of heavy trains.
6. Electric braking on long descending grades.
7. Elimination of helper locomotives over ruling grades.

These desirable locomotive features are produced by the electric transmission. The same characteristics could be obtained with electric transmission from any other type of power plant. It is not the purpose of this comparison to decry the many important contributions to railway operation which have been made by the Diesel engine, but to point out the significant contribution of the electrical transmission which is not too universally appreciated or understood.

Figure 9 shows why electric transmission is so important. One curve on this chart shows the ideal speed-tractive effort of a 4,000 horsepower locomotive. This ideal curve represents a constant horsepower at all locomotive speeds, a characteristic which would secure full utilization of the locomotive's inherent capacity under every operating condition. No existing prime mover will meet this performance with direct mechanical drive. The reciprocating steam engine most closely approaches it, which accounts for its long survival in land transportation. Also shown by Figure 9 is the typical performance of a Diesel engine with any form of direct mechanical transmission. This performance in itself is not suited to traction purposes, but through the use of the electric transmission can be converted into the ideal performance except for that loss in efficiency encountered in the drive apparatus.

Figure 8. Modern main line locomotives

(Top) Diesel, 6,000 horsepower
(Bottom) Turbine electric, 6,000 horsepower

The Diesel electric has no equal for train switching service. Locomotives of 660–1,000 horsepower replace steam power of considerably greater capacity. These locomotives operate for long periods without attention. Their refueling is simple, their maintenance expense is low, their efficiency is high, and their standby losses are nil. With such favorable operating expenses, they promise to replace all other types in switching service. Diesels are also rapidly extending their operation to road service. In these applications, the locomotives range from 1,500 to 6,000 horsepower composed of one or more units of 1,500, 2,000, or 3,000 horsepower capacity. The average size of all road locomotives is between 4,000 and 4,500 horsepower.

The phenomenal increase in the use of diesel motive power is illustrated by Figure 10. Those few railroads with electrifications have long appreciated the electric transmission and the advantages which it provides. The Diesel electric locomotive is extending these advantages on a world wide scale.

Steam Turbine-Electric Locomotive

The coal-burning steam locomotive has now adopted electric drive. In 1947, the Chesapeake and Ohio received the first coal-burning steam turbine locomotives having a rated capacity of 6,000 horsepower. These locomotives will haul high speed, streamlined passenger trains on exceedingly exacting schedules.

The locomotive arrangement itself is quite novel. Coal is carried at the front end, followed by the operator's compartment. The boiler is next in line, and the turbine-generator plant at the rear. A separate tender carries water. Eight axles are equipped with traction motors.

In 1944, the Pennsylvania Railroad introduced the first geared turbine locomotive of large capacity. Experience with its operation has shown that a turbine will operate reliably and at low maintenance in locomotive service. With electric drive, the turbine should give equally satisfactory performance.

In many countries, coal is the one assured, long range source of fuel. Improvement in the coal-burning locomotive to make it thoroughly competitive with the Diesel will be welcomed by roads so

Figure 9. Ideal 4,000 horsepower locomotive performance versus Diesel engine performance

Figure 10. Diesel locomotive units operated by class 1 railroads

situated. The Chesapeake and Ohio locomotives will be watched with interest by railroad men everywhere.

A more efficient utilization of coal could be secured by the adoption of a high-pressure high-temperature boiler. Extensive work is now under way on this problem and if it is satisfactorily solved, the coal-burning locomotive could easily return to popular favor. The high-pressure steam locomotive, when it appears, will undoubtedly utilize a turbine-electric drive, thus, a return to favor of the steam locomotive should further increase the use of electric equipment by the railroads.

The Gas Turbine Locomotive

From the long range viewpoint, the possibilities of the gas turbine locomotive are most attractive, including:

1. Elimination of the boiler, substituting in its place a means to utilize the products of combustion directly in the prime mover.

2. Elimination of all reciprocating machinery, substituting therefore purely rotating apparatus which, when once perfected, normally operates at low-maintenance expense and for long periods without attention.

3. A prime mover with excellent weight and space characteristics which should permit locomotives of large capacity to be built in one unit.

4. For the first time, a means becomes available to burn low cost fuels in locomotive service at high efficiency.

The gas turbine locomotive is coming. One manufacturer has had a 2,000 horsepower turbine generator set operating on the test floor for almost two years. Bituminous Coal Research is developing two coal-burning gas turbine locomotives. Several turbine manufacturers have plans to equip locomotives in the near future.

Probably the first gas turbine locomotives will be oil fired. Later models will burn coal. This sequence will be dictated by the greater ease with which liquid fuels can be satisfactorily burned.

The gas turbine eventually will prove to be a strong competitor of all other types. It has so many potential advantages that its place in the transportation picture cannot be denied. But, before proved commercial units are available, extensive development will be required. At first, fuel economy will not be as good as the Diesel, but that will be compensated

Figure 11. Horsepower of traction motors operated by class 1 railroads

by lower maintenance, and will improve with further development.

Electric drive is equally advantageous to the gas turbine locomotive. When the simple open-cycle gas turbine is used, which seems to be preferred in locomotive design, this transmission is a necessity because of the inherent speed-torque characteristics of this type unit. This new type of motive power also will extend, not restrict, the trend of the railroads towards the movement of traffic with electric drives.

Trends in Motive Power

Electrical engineers have dreamed for many years of the day when the railroads might be electrified. Unless something halts the present trend, that day may come, with electrification consisting partly of electric locomotives receiving their power from a central power station, and predominantly from electric locomotives carrying their own power plants.

Figure 11 shows the total horsepower of traction motors used by the railroads of the United States. Until 1936, this curve represents primarily the extension of electrification. After 1936, it represents electrification and Diesel electric locomotives. In 10 years, the total capacity of the diesel locomotive motors has greatly exceeded that of electrification, and by the end of 1948, approximately another 3,000,000 horsepower will be added. Should all locomotives eventually be converted to electric drives, the installed capacity of electric motors on the railroads would exceed 125,000,000 horsepower, or almost twice the installed capacity of all central power stations.

Literally, a revolution is taking place in the motive power field. An interesting fact is the importance of the electric drive in this change. Its advantages have been so well demonstrated and accepted by the railroads that its position seems invulnerable to the possible vicissitudes in the fortunes of the various prime movers. Whether the railroads electrify or use steam, Diesel or gas turbine prime movers, their motive power will be propelled by electric traction motors to a rapidly increasing degree.

Conclusion

A brief summary of the uses for electricity by land transportation services has been presented for the United States. It would have been even more desirable to present similar figures for the railroads of the world, but unfortunately, accurate data on a world-wide basis are unattainable. It was felt preferable, therefore, to give an adequate picture as it applied to one country rather than a more universal picture which, of necessity, would be both inaccurate and inadequate.

The land transportation industry, with an installed capacity of 175,000,000 horsepower, constitutes the nation's greatest user of power. In the not too distant future, with an uninterrupted continuation of present trends, this industry also will become the nation's recognized leader in the use of electric equipment.

Standardization in the United States

H. S. OSBORNE
FELLOW AIEE

Synopsis: Standardization in Mexico extends back over a considerable number of years. In 1926 the Secretariat of Industry and Commerce prepared a National Electrical Code which has been influential in guiding Mexican progress ever since. In recent years, standardization in a broad field has been an important activity of the Ministry of National Economy which in 1943 established the Direccion General de Normas, (DGN). Under the initiation of DGN and with the co-operation of Mexican industry and professional organizations more than 100 standards have been adopted to guide Mexican federal government purchases, covering a wide range of commodities.

Scope of this Discussion

THE term standardization may be applied to very broad and diverse fields of activity. We will consider primarily the development of technical standards, namely, those types of standards of most interest to the AIEE and other electrical engineering societies. As a general background, however, this paper refers to the activities of the American Standards Association and of the organizations associated with it, activities which cover a far broader field.

In the field of electrical standards the AIEE has long been a leader. The first standards for electric machinery generally accepted in the United States were produced by the AIEE in 1899, and the Institute has a record of continuous activity in producing standards in the electrical field since that time. Recognizing the growing importance of standards and particularly the importance of a generally accepted means of establishing the national recognition of standards, the AIEE was one of the small group of organizations which formed the American Engineering Standards Committee in 1918. It has subsequently helped that committee and its successor, the American Standards Association (ASA) to develop to meet the increasing responsibilities of a rapidly growing national standardization movement.

Purpose of a Standard

Basic to the methods and procedures used in the United States is the fact that to receive national acceptance, standards must be designed to serve the interests of the nation as a whole. Similarly, international standards must be designed to be helpful to interested groups throughout the world.

The procedures to be followed in establishing a standard naturally partake of the nature of the society which they serve. In a democratic society all standards to be effective must represent a general consensus of expression of those most concerned. This applies even to those types of standards which are incorporated in government regulations. It applies with much greater force to the standards which in the free economy of the United States constitute the great bulk of the work of standardizing groups, namely, voluntary standards developed by those most concerned and depending upon their voluntary acceptance for their use.

The subject matter of a standard may be methods of measurement, terminology, dimensions, and other physical characteristics, operating practices, provisions for safety or any other of a very wide range. Whatever the subject matter, the standard is an expression of the current view of those best informed on that subject as to what is most desirable for the advancement of the industry and the elevation of living standards of the people. Where there are differences in opinion among those representing different groups, the standard must represent a conscientious effort to find the solution rather than merely a compromise between conflicting claims. Furthermore, such a standard is dynamic, not static, and it should be modified promptly as the result of further information or changes in conditions.

Methods

The ASA grew out of recognition of a need for a formalized procedure to determine when a standard meets the outlined requirements and an organization to certify to this fact. The basic control of the Association is in the hands of its member bodies; 64 nationwide associations and groups of associations widely interested in standardization work. These member bodies include 14 professional societies, 40 trade organizations, and 10 departments of the federal government. In addition, more than 2,000 companies and individuals are associated in this work as members in various classifications.

The basic principle of operation of the ASA in the approval of a standard as an American Standard, is that all groups vitally concerned in a given standard, must have been consulted and given an opportunity to express their views, and that the standard itself must represent a consensus of these interested groups. In the practical application of this principle of consensus the work must be broken up into sufficiently small parts so that all interested in each part can participate effectively.

It has not been found possible to draw a hard and fast line as to the degree of unanimity necessary to justify the certification of a standard as an American Standard. All those concerned must

Paper 48-136, recommended by the AIEE standards committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 20, 1948; made available for printing March 23, 1948.

H. S. Osborne is chief engineer, American Telephone and Telegraph Company, New York, N. Y.

have been given full opportunity to express their views, and where there are individual objections these must have been fully considered by all of the group. If, after weighing these objections, they have been rejected by all but a very small minority, it is considered that the consensus is established. In determining whether a minority is sufficiently small to be overruled it is necessary to take into account the nature and extent of the interest represented by the dissenting votes as well as their number.

Procedure

Under the broad principle that a consensus must be established, the procedures of the ASA recognize a wide variety of methods by which the interested groups formulate standards which are to be submitted for approval as American Standards. Any method which meets the broad requirements is acceptable.

The procedure which is most widely used is the formation of a sectional committee under one of the standards-making organizations as sponsor. The sponsor organizes the committee, which is approved by the ASA as adequately representing all interested groups, consumers, producers, government departments, distributors, insurance companies or others, depending upon the nature of the subject matter. When this committee has completed its work and the resulting standard is approved by the sponsor, the evidence as to the degree of unanimity is submitted to the ASA with the request that the standard be approved as an American standard.

In the electrical field, standards for electric machinery, which were first produced by the AIEE, also are of very direct interest to other associations representing manufacturers and the power companies. Before the organization of the ASA, competition had grown up between these organizations in the preparation of standards. It was therefore arranged that as a part of the ASA there would be an Electrical Standards Committee in which all of these groups were represented. The Electrical Standards Committee recommends to the ASA the sponsorship for each case and in some cases assumes sponsorship itself where this is considered desirable, rather than having the work carried on by a single organization.

Similar correlating committees have been developed in other fields of work, providing expert agencies of the ASA in these fields. The fields represented at present are mechanical, safety codes, building codes, mining and consumer goods.

Relations Between Industry and Government in Standardizing Work

In all of this work, government departments and bureaus participate on the same basis as any other organized technical group or industrial group. Participation in the development of each standard is open to all those who have an important interest. Those who can contribute information or work are urged to take an active part. At the present time 50 government bureaus are officially represented on committees responsible for 350 standards.

International Work

As the ASA is the focal point of national standardizing work, and its members include a large number of organizations most active in and concerned with the development of standards, it is an ideal association to represent the United States in the development of international standards. The ASA was active in the recent formation of the International Standards Organization (ISO) and H. Coonley, Chairman of the Executive Committee of the ASA, was elected the first President of the new international organization. Mexico is also a member of the ISO.

For many years, the International Electrotechnical Commission (IEC) has been the authoritative body for carrying out international standardization in the electrical field. The same electrical organizations which carry out the national standardization work in the electrical field in the United States, by cooperation through the procedures of the American Standards Association, have also for many years been the principal contributors, both in work and in money, of the United States National Committee of the IEC. Accordingly, it was arranged that this committee should become an integral part of the ASA. This desirable integration of acitivities took place in 1930 and has proved advantageous. It is now anticipated that a similar integration will take place between the IEC and the new International Standards Organization, the IEC remaining, however, the authoritative vehicle for international standards in the electrical field.

Conclusion

All of this work represents a growing appreciation in the United States, as in many other countries, of the importance of standards both in improving the economic condition of the country and also in helping to stimulate international trade and improve economic conditions generally throughout the world. Important ways in which standards are helpful include the following:

1. To create understanding and avoid disputes. For example, a purchaser can use standards as a basis of stating exactly what he is ordering and determining whether or not he receives what he ordered.

2. Improve working conditions. Numerous important safety standards emphasize this point.

3. Assist in the economy of production. Standard dimensions, methods, and performance characteristics all tend in this direction.

4. Increase convenience of use. Interchangeable parts and standards of quality illustrate this point.

5. Reduce trade barriers within a country and to the extent that they are used by many countries internationally.

6. Important for defense. This applies not only nationally but internationally to standards used in common by groups of countries who may have occasion, as in the two recent World Wars, to join together to defend themselves against an aggressor.

The ASA has given special emphasis to developing the closest possible ties in standards work between the United States and the other republics in the western hemisphere. With this in view, the Association has had for several years a Latin American department. The purpose of this department is to stimulate rapid interchange of information on the progress of standards work in the various countries, arrange for translations of standards from English into Spanish and Portuguese and vice versa, and always to stimulate the closest co-operation between the standards-making bodies in the various countries. The importance of standardization is widely recognized in the countries of North and South America and is indicated by the fact that seven of these countries have national standardizing bodies Argentina, Brazil, Canada, Chile, Mexico, United States, and Uruguay.

Co-operation between Mexico and the United States was discussed at the Mexican-American Conference on Industrial Research held in Chicago in October, 1945. I hope that this discussion which may in a sense be considered a return mission to Mexico, will further stimulate co-operation in standards work in the two countries, adding one more tie to those which closely bind together these two friendly neighbors.

No Discussion

Trends in Electrification of American Steel Industry

L. A. UMANSKY
FELLOW AIEE

THE STEEL INDUSTRY in the United States is largely electrified. It is one of the largest users of electric power. For instance, in 1947 this industry has produced close to 85,000,000 net tons* of steel and has consumed approximately 200 kilowatt-hours per ton, or a total of about 17,000,000,000 kilowatt-hours. Only one other group of industries, the electrochemical, rivals steel as user of electricity.

This well established partnership of electricity and steel is not a mere coincidence. As will be shown later, it is based on sound engineering and economic factors. Nor is their partnership new; 25 years ago close to 90 per cent of power applications in the steel industry were motorized. Yet, during these 25 years, the type of electrical equipment used in the industry has radically changed. This equipment became more intricately connected with the steel manufacturing processes. More than that, the processes themselves had been redesigned around the electrical equipment, in order to make full use of its advantages.

This paper attempts to give a brief review of these changes and to point out the role of electricity in improving the processes and in lowering the production costs.

Generation and Purchase of Electric Power

Basic Facts

An integrated steel plant starts with iron ore, coal, and limestone as the principal raw materials, and ends up with finished rolled-steel products. The main component parts of such plant are coke ovens to convert coal to coke and by-products, blast furnaces to convert iron ore to pig iron, open hearth furnaces to produce steel out of pig iron and scrap, and rolling mills to give the steel the needed shape and form.

The natural by-product of a blast furnace is gas. While it is not very high in heat content (about 90 to 100 Btu per cubic foot), it is produced in such large volume that a sizable portion of it is usually available for power generation. On the other hand, the rolling mills are large users of power. They are usually located some distance away from the blast furnaces. Thus, a power house near the furnaces, electric transmission of power to the mills, and electric mill drives is the logical and accepted arrangement.

To better understand the relation between the heat balance of a steel plant and the generation of power, the following figures should be helpful.

To produce a ton of pig iron the industry has used an average of 1.725 tons of iron ore, 0.934 ton of coke, 0.41 ton of limestone, and, last but not least, 4.5 tons of air. In 1947 the United States blast furnaces have produced about 58,500,000 tons of pig iron; about 10 per cent of this amount being used as "merchant iron" in foundries. Thus, some 52,500,000 tons of iron were left for converting into steel in open hearth and electric furnaces and in Bessemer converters. Since 85,000,000 tons of steel were produced in the same year, the pig iron contributed only 62 per cent of this amount; the balance, or 38 per cent, was made up of scrap.

The 85,000,000 tons were the weight of steel ingots as poured from melting furnaces. By the time this steel has been rolled, trimmed and sheared, the weight of the finished products, shipped from the steel mills, became only slightly over 63,000,000 tons. The "loss", or 22,000,000 tons, constituted part of the scrap needed for feeding the melting furnaces.

Now these figures are the average of the whole steel industry. They may not be true for all, or for any, specific mills. This fact should be firmly kept in mind. The "average" steel plant which will be presently discussed is merely a hypothetical plant.

Waste Gas as Source of Power

Let us assume that this plant produces 0.6 ton of pig iron for every ton of steel ingots. The corresponding amount of blast furnace gas is about 70,000 cubic feet. Not the entire volume of gas is available for power generation; about 50 per cent is used for serving the blast furnace itself; for pre-heating the air blast required for furnace operation, and for generating steam to drive the turbo-blowers. The remaining 50 per cent of gas could be used for power generation, if there were no other equally legitimate demands for this gas around the steel plant.

The 50 per cent of 70,000 cubic feet, at 95 Btu per cubic feet, will give us 3,330,000 Btu. Allowing 17,000 Btu per kilowatt-hour, generated in a steel mill power house, we could produce about 195 kilowatt-hours per ton of steel ingots.

Theoretically, this could just suffice for operating the steel plant. Actually, the amount of generated power will fall short of this amount. The present tendency is to give priority to the use of gas for heating purposes, at the soaking pits, coke ovens and reheating furnaces. This reduces the share of gas available for power generation. Furthermore, it is not possible to rely on the "average" figures as we have done in the foregoing ex-

*Throughout this paper "ton" refers to the "net" or "short" ton of 2,000 pounds. The "long ton" used previously is 2,240 pounds, while the "metric ton" equals 1,000 kilograms or 2,205 pounds.

Paper 48-141, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted March 9, 1948; made available for printing March 23, 1948.

L. A. Umansky is with the industrial engineering divisions of the General Electric Company, Schenectady, N. Y.

Figure 2. Electronic frequency changer in a steel mill for interconnecting the 69-kv, 60-cycle, and 44-kv, 25-cycle systems

Two 10,000-kw units installed in brick-walled section of the steel tower

ample. Many power consuming departments, such as rolling mills, are ordinarily not working during week ends, while the blast furnaces are on a seven-day schedule. The ratio of pig iron to steel varies from plant to plant. The total power consumption per ton of steel also varies, depending on the kind of finished product.

Some integrated steel plants, complete with blast furnaces, produce heavy steel sections such as rails, structural shapes or large merchant bars. These plants require considerably less than 200 kilowatt-hours per ton of ingots, and plants of this type may be more nearly self-contained in generating their own electric power. Conversely, other plants, producing smaller sections and particularly light flat products, like sheets and tinplate, require more additional power. Since the proportion of these light sections in the American steel industry is growing, the need of additional power, generated from coal or purchased, also goes up.

The long range trend in the steel industry as a whole is in favor of purchasing this additional power rather than generating it from burning coal. The rising cost of coal and labor, the continuing low cost of purchased power, the desire of steel companies to apply their investment capital for steel making and processing facilities, readily explain this trend.

In addition to the blast furnace gas, a steel plant has a few other, less important, sources of by-product fuel or heat, as well as other demands for them. However, their presence does not change the general picture. Coke breeze is usually burned under boilers as a supplementary fuel to blast furnace gas; waste heat boilers in open hearth furnaces can produce some additional steam; coke oven gas and tar, being too valuable, are not burned under boilers. Some steam is needed for miscellaneous processes and for heating of buildings.

Some 25 years ago the American steel industry, taken as a whole, generated approximately two thirds of all electric power which is consumed. At present this proportion has dropped to about 50 per cent. In spite of this trend many steel mills have power plants well in excess of 100,000 kilowatts installed, and these plants are growing. Turbogenerators of 30,000, 40,000 and 50,000 kw are encountered, although units of 20,000–25,000 kw are more representative. A number of gas engine generators, operating on blast furnace gas, are still in service, but it is questionable whether many units of this type will be installed in the future.

Character of Steel Mill Load

From the viewpoint of power supply, whether from its own power house or a public utility connection, the steel mill load has good characteristics. For example, the ratio of peaks to average demand is not excessive. The following example may serve as a rough guide.

Assume an integrated steel plant rated to produce 1,000,000 tons of steel ingots annually and operating at capacity. Allowing 200 kilowatt-hours per ton, the total power consumption should be close to 200,000,000 kilowatt-hours per year. If spread over 8,760 hours, the average load would be 23,000 kw. If week ends and annual holidays are not counted, leaving us about 7,000 hours, the true average during the working period will be some 25 per cent higher, or 28,500 kw. Of course, the load is not constant even during this period; we can expect the maximum 1-hour demand to be some 20–25 per cent higher than the working day average, or about 35,000 kw. Finally, we should encounter momentary peak loads of about 150 per cent of the working day average, or about 43,000–45,000 kw. The power house or the tie with the power company should be designed accordingly.

Quite obviously, when the steel plant operates below its rated capacity, the average load goes down rapidly while the maximum demand is apt to remain high.

Frequency

Many large steel plants built in the period 1900–1920, when electrification was making its first strides, have selected 25 cycle as the preferred frequency. Since most of these plants were of the integrated type, with their own power houses, and since ties with utility systems were not considered then as important as they are now, the steel industry had a free hand in making this choice.

The 25-cycle system was chosen primarily from the viewpoint of rolling mill drives. Induction motors were almost universally used. Low-speed motors for direct drive were preferred since reduction gears were not considered then as sufficiently reliable. These factors obviously favored the lower frequency than the conventional 60 cycle.

On the other hand, many smaller steel mills without power houses of their own and relying on purchased power had to adopt even then the normal frequency of 60 cycle. Quite a few of them grew to be large plants since that time, but of course carried on with that frequency.

Under present conditions the use of 25 cycle offers little advantage. The contrary rather is true. The design of gears

has reached a high degree of perfection and reliability. In many cases, even when low-speed motors are employed, the synchronous motors can be successfully applied, and these are not penalized by the combination of low speed and normal frequency. Furthermore, fewer and fewer a-c drives are used, their place being taken by d-c machines, as we will see later. A synchronous motor-generator to supply power to d-c machine can be built as well or better for 60 cycle as for 25 cycle.

The 60-cycle turbines, motors and transformers cost less than their 25-cycle counterparts. Being standard in the industry they are more readily available. Higher motor speeds, such as 3,600 and 1,800 rpm, are possible as against the maximum 25-cycle speed of 1,500 rpm. Greater choice of speeds is offered. Many pieces of machinery, as for instance pumps, fans, and machine tools designed for general use with 60-cycle motors are made available for steel mills adopting this frequency.

It is not surprising, therefore, that the 60-cycle frequency is rapidly gaining ascendancy in the steel industry. No new plant built in the last 20–25 years employs 25 cycle, except of course for some extensions of the older plants. Many other mills have ceased adding to their 25-cycle systems, and are using 60-cycle power for their new additions. If 25 years ago the ratio of 25 to 60 cycle capacity installed in the steel industry was 2 to 1 or more, this ratio is now less than 1 to 2 and is rapidly growing smaller.

This change entails the use of frequency changers for tying together the 25- and 60-cycle systems. Ordinarily, the steel plant continues to supply 25-cycle power to its older mills. New additions are connected to either purchased 60-cycle power or to the new 60-cycle generators of the plant. In either case, the interchange of power between the two systems is essential in order to increase the effective reserve capacity at the power house, and to have greater flexibility in operating the newer and more efficient generating units.

Several types of frequency changers may be considered. The simplest and the least expensive is the synchronous-synchronous unit. It permits of flow of power in either direction and is also suitable for stub-end feed operation. However, the 25-cycle systems do not maintain their frequency as well as the newer and larger 60-cycle systems. Variations from 24 to 26 cycle are encountered. This imposes severe duty on the frequency changer. Experience dictates that the capacity of the latter should be not less than 25 per cent of the generating capacity on the smaller of the two systems. The control of the flow of power has to be done by the governors on the 25-cycle turbogenerators. A more flexible frequency changer is of the Scherbius type. The 60-cycle unit is a synchronous machine connected to a 25-cycle slip ring induction motor. The latter has its rotor circuit connected to an a-c regulating machine of the commutator type. By suitably controlling this machine, it is possible to control the magnitude and direction of the flow of power through the set, regardless of variations of supply frequency. It is also possible to supply power to either system in the stub-end fashion, without any synchronous machine being then connected to the system. A 12,500-kw unit of this kind is in successful operation in one large steel plant near Pittsburgh, Pa.[1]

Last, but not least, is the electronic frequency changer. This equipment consists essentially of two rectifiers connected through transformers to the respective power systems. The d-c ends of the two units are linked together. At any given time one unit acts as an a-c to d-c rectifier, while the other as a d-c to a-c inverter. The flow of power is controlled by phase control. This equipment is also of the asynchronous type, that is, the flow of power can be controlled independently of frequency variations on either system. The flow of power may be reversed at will, but the converter must receive reactive kilovars from both systems. Thus, it is not readily suitable as a source of stub-end power supply. Two 10,000-kw frequency changers of this type are in successful operation for about six years in a large steel plant near Pittsburgh while another unit of 6,700-kw capacity is operating for about the same length of time near Chicago, Ill. Being a static device, the electronic frequency changer does not require heavy foundations. As shown, the two 10,000 kw units are mounted in a steel tower, tying the 69-kv, 60-cycle, and 44-kv, 25-cycle transmission lines.[2]

The chief drawback to the wider use of this type of equipment is the drain of kilovars from the systems and its unsuitability for stub-end operation.

System Voltages

Two voltages were always popular and widely used in the steel industry: 2,300 and 6,600 volts. The former voltage originated in smaller plants which were not expected to grow larger, but often did in defiance of these expectations. Quite obviously, the 2,300-volt system could not very well keep pace with the growth of the plant. The larger steel plants have chosen, as early as 40 years ago, 6,900/6,600 volts as their voltage.* This volt-

*When speaking of generator or system voltage, it is correct to use the values of 13.8–11.5–6.9–2.4 kv and 480 volts. The corresponding voltage ratings of motors and other power utilization equipment are 13.2–11.0–6.6–2.3 kv and 440 volts.

Figure 3. (left). Cumulative curve of rolling mill drives

Figure 4. 10,000-horsepower twin-motor drive for a large reversing slabbing mill

Each roll is driven by a separate 5,000-horsepower 40/80 rpm motor

age is still by far the most popular in the steel industry, and is used frequently for power generation and distribution, as well as for large motor drives. As the plants and systems grow, the adequacy of this voltage for all three purposes becomes questionable.

Turbogenerators of 20,000–30,000 kw (not to speak of larger units) lend themselves better to a voltage of 13.8 kv rather than 6.9 kv. Bus runs from the generators to the switchgear and the switchgear itself are definitely less expensive at the higher voltage.

Considering the available standard and well developed apparatus, it is highly desirable to limit the circuit breakers at the mill substations and for large motor drives to the 500,000-kva rating available in the metal-clad form, both for 6,900 volts and higher voltages. However, on large 6,900-volt systems, the factor limiting the circuit breaker selection is more often than not, the momentary asymmetrical fault current, rather than the interrupting capacity. To cope with this limitation a greater sectionalization of circuits or an excessive size of current limiting reactors become essential. At voltages like 11.5 or 13.8 kv, these problems seldom occur. Better circuit arrangement and better switchgear selection is made possible. It is, of course, obvious that the cost of feeders is lower with the higher voltage.

As far as large motors are concerned, the use of 6.6-kv voltage is satisfactory from about 1,000 horsepower and up to the largest size ordinarily encountered in steel mills. For small and medium size motors 440 volts is usually supplied. There remains a twilight zone, 500–1000 horsepower, where 440 volts is low, while 6,600 volts is to high for best all-around results. Compromises are usually made for this range of motor sizes since very seldom an intermediate voltage like 2,300 volts is introduced between 6,600 and 440 volts.

However, when 13.8 or 11.5 kv is used for distribution, an intermediate voltage (2.4/2.3 kv) becomes practically mandatory and a more versatile "3-voltage-standard" is established for the plant. Under this standard the large motors (synchronous 2,000–2,500 horsepower and larger, induction 3,000–3,500 horsepower and larger) can be chosen for 11-kv or 13.2-kv operation, medium size motors down to about 200 horsepower can be built for 2,300 volts and for the smaller motors the low voltage of 440 volts can be used of course. For supplying the 2,300-volt and 440-volt power, localized distribution systems are then provided, energized from load-center step-down transformers. These low-voltage systems, being local, do not extend over the entire plant as the main high-voltage distribution system does.

For a large new steel mill, of say 1,000,000–2,000,000 ton annual capacity, with generating capacity up to about 75,000 kw (or equivalent tie-line with public utility), a 3-voltage power system of 13,800–2,400–480 volts can be well recommended.

Several steel mills, which have originally started with a 6,900-volt system, have now grown to such large size that the power demand exceeds 100,000 kw. Considering the already made large investment in 6,900-volt equipment, it is sensible for these large plants to leave most of this equipment intact (if otherwise adequate), but to replace the 6,900-volt distribution system with a higher voltage, such as 24 kv, 34.5 kv, or even 69 kv, and to provide several major substations stepping down from this high voltage to 6,900 volts. This means, in effect, splitting the plant in electrical sense into several smaller units, tied together by the high-voltage "backbone."

Several large steel mills have already adopted this system of modernization.

Rolling Mill Drives

The major portion of power supplied to a steel plant is consumed by the rolling mill drives; that is by the work of shaping and otherwise processing the steel from ingots to finished rolled products, such as sheets, bars, rails, structural shapes, and rods. Electricity plays a predominant part in this work.

Even 20 years ago more than 90 per cent of the rolling mills were electrified. Since 1929 to 1947 the installed capacity of the drives has increased about 250 per cent, while the ingot production went up only 50 per cent. Several reasons explain this fact.

In the first place, as already noted, the industry now converts a greater portion of its tonnage into light flat rolled sections, such as sheets and strip, requiring greater power for rolling. In 1925 these products comprised 17 per cent of the total finished steel, in 1947 this percentage increased to 28.9. Secondly, many rolling methods have radically changed, calling for vastly

Figure 9. Layout of a recently designed rod mill

11 d-c motors are driving the 17-mill stands

differing mills and for more powerful and numerous drives.

A brief review of these trends is given in the following.

Reversing Drives

The principal application of these drives is to blooming and slabbing mills, which roll reheated ingots into such semifinished products as blooms and slabs. Reversing plate mills, rail mills and the like also fall in this category.

In general, one may conclude that these types of drives have maintained their principal features. The mill is driven by a low speed, directly coupled d-c motor or motors, supplied with power from one or more d-c generators. The latter are driven either by an induction motor equipped with a heavy flywheel, or in some cases by a synchronous motor Field control of the d-c machines provides means of reversing the drive and of adjusting its speed.

A closer analysis of many of the late installations will show that new and fruitful ideas were introduced and put in practice in the last quarter of the century.

The so-called twin drive should be mentioned first.[2] With this arrangement the top and bottom rolls of the mill are driven by a separate motor; nothing but the hot metal ties the two rolls (and the two motors) together; yet the electrical control keeps the two motors in step and successfully divides their load evenly. The pinion stand (the 1-to-1 gear unit conventionally tying together the rolls in the mill) is eliminated; thus the mechanical equipment is simplified and maintenance is reduced by a wider use of electric means. Seven such equipments are in successful operation in the United States, the largest being rated 10,000 horsepower at 40/80 rpm. This number does not include cold strip mill drives, of which more will be said later. A still larger drive has been provided for a reversing roughing stand of a plate mill, rated 7,000 horsepower, 25/50 rpm, which is capable of developing a maximum torque of approximately 4,000,000 pound-feet (550 ton-meters), which is believed to be the highest value of torque of any mill drive.

The most noteworthy development in the control of these mills has been the wide use of rotating regulators and amplifiers (such as amplidyne). Separate exciters are usually provided for the reversing motors and for the corresponding generators. The fields of these exciters are under control of several amplidynes arranged to get these principal results:

1. Extremely quick acceleration and reversal of the mill. (For instance, a 10,000 horsepower, 40/80 rpm drive reverses from plus 40 rpm to minus 40 rpm in less than $1^1/_4$ seconds.)

2. Effective limitation of current peaks beyond the capacity of the machine.

3. Maintenance of mill speed regardless of flywheel speed regulation.

4. Great simplification of control apparatus.

The use of synchronous motor-generators instead of flywheel sets has made some gains. The largest reversing drive so equipped is a 6,000 horsepower structural mill with an 7,500 horsepower synchronous motor driving the motor-generator set. With the steel mill power systems growing rapidly, an occasional peak load of, say, 250–300 per cent normal can be readily absorbed, while taking full advantage of lower first cost, lower maintenance, and leading power factor of the synchronous versus flywheel set. By automatically controlling the excitation of the synchronous motor as function of load, the effect of the peak loads on the system voltage is reduced to a minimum. This has been very effectively done, for instance, through the use of an amplidyne power factor regulator for a 4,000 horsepower reversing mill drive.

Synchronous Motor Drives

It is hard to realize that 25 years ago the use of synchronous motors for driving rolling mills was actually unknown. Since 1925 they were successfully applied to a great variety of mills; continuous skelp, billet and rod mills, usually driven through a line shaft; tube piercing mills; roughing stands of some hot strip mills, and many others.

Prior to that time only slip ring induction motors would be considered for such constant speed drives. Now the use of

synchronous motors is rather the rule, while that of induction motors is the exception, which is followed only when flywheels actually are needed for the sake of peak load limitation.

The successful entry of synchronous motors into this field was due, primarily, to a better design of starting and running characteristics. A hot rolling mill is never started under load, that is, with the metal in the rolls. A starting or break-away torque of 50 per cent normal, or less, is usually sufficient, with few exceptions such as rod mills, where torque values up to 75 per cent might be needed. These torques, or even higher ones, are not difficult to provide. It is important, however, to maintain a high "torque efficiency", that is, a high ratio of starting torque to starting current, both being expressed in per cent of normal values. Otherwise the current inrush when starting a large motor, while maintaining sufficiently high torque, might become excessive for the power system.

The maximum running or "pull-out" torque of 200–300 per cent normal, depending on the type of mill, can be readily provided.

Some very notable applications of synchronous motors were made, with ratings as high as 9,000 horsepower at 107 rpm, 6,500 horsepower at 187 rpm, and many others. Figures 5 and 6 show a mill layout and a 4,500 horsepower, 400 rpm motor driving a rod mill; a typical example of a constant speed mill, rolling a large tonnage of products of rather limited variety.[4]

From the viewpoint of synchronous motors it is rather unfortunate that their usefulness for rolling mill drives became well established only at the end of era of constant speed drives in general. Even as late as 1931, of all the new drives purchased 32 per cent were of constant speed type, while in 1947 this percentage dropped below 14. This shows the ever growing trend toward adjustable speed equipments.

Adjustable Speed Drives

The advantages of operating rolling mills through a range of adjustable speeds were well recognized even before the period which we are considering. Electrical engineers had developed suitable drives for such mills as were in use at that time.

The technological developments in the art of rolling, the redesign of mills for greater operating flexibility and speed, and the greater reliance of mill designers on the electrical equipment have radically changed the type of electric drives.

A quarter of a century ago many mills, even though electrically driven, were still of the type designed originally for steam engine drive. For instance, a merchant mill shown in Figure 7 has ten stands through which the metal passes consequently, being reduced from billets having a cross section of, 4 by 4 inches, or thereabouts, to small rounds, flats or angles. All ten stands are geared to a common lineshaft which is driven by a single motor rated 4,500 horsepower, 300/500 rpm. When such large capacity is concentrated in one or two drives, and speed adjustment not exceeding 2-to-1 is sufficient, it is usually most economical to build them of the a-c adjustable-speed type, either of the Kraemer or Scherbius system.[5] However, the growing trend during the last 25 years has been to split the total drive capacity into smaller units, to drive almost every stand by a separate adjustable speed motor (Figure 9), eliminating line shafts and many gears. With individual speed adjustment of each stand available, greater flexibility in selecting rolling schedules is feasible. Thus, a greater variety of products can be successfully rolled on the same mill While each of the driving motors is smaller, the total installed capacity is naturally greater than with a group drive, since no advantage can be taken of the diversity load factor of the several stands.

Such arrangement invariably leads to the choice of d-c drives, supplied with adjustable voltage power from one or more motor-generators. As compared with the a-c adjustable speed systems (if the latter were considered for these new mills), the multidrive d-c arrangement is simpler and is more economical. The over-all number of machines involved is smaller, the cost of high voltage switchgear is reduced, and the possible speed range is increased.

This explains the twilight of the speed-controlled a-c drives so popular some 20–25 years ago, and the ascendency of the d-c drives which came into practically universal use during this period.

The majority of these drives are designed for 600 volts and this voltage can be almost considered as "standard" for steel mill applications. A few 750-volt installations have been made. For small drives, about 200 horsepower and smaller, 250 volts may still be considered.

Use of Rectifiers

Since the use of d-c drives for rolling mill drives is so widely spread, it is natural to consider the application of rectifiers to supply power for these drives. Several successful installations of this type have been made, but it is far from correct to claim that the rectifiers have replaced the synchronous motor-generators.

The rectifier has the advantage of higher efficiency over motor-generators,

Figure 10. Two 3,500-kw 600-volt rectifiers supplying power to a hot strip mill

Figure 11. Old-fashioned sheet mills requiring large amount of hand labor

Figure 12 (left). Layout of an 80-inch wide modern hot strip mill, driven by twelve main motors totalling 39,000 horsepower

Figure 13. General view of a modern hot strip mill, delivering steel at speeds up to 2,000 feet per minute

particularly at 600 volts. Low running light losses are particularly advantageous. The installation costs are lower, since no heavy foundations are needed. Since rectifier losses are removed by cooling water, the problem of motor room ventilation is simplified. The absence of commutators, brushes, and bearings on the converting equipment lowers the maintenance costs.

On the other hand, the rectifier is handicapped by a somewhat lagging power factor about 95 per cent, instead of the leading one on the motor-generator. This may or may not be of importance, depending on the over-all power factor of a given steel plant. Voltage control is very easily obtained with the generators. With the rectifiers it is necessary to use phase retard which lowers the power factor as much as it lowers the voltage, or, transformer taps should be used, which method adds to the cost and is not as flexible as the generator field control.

Since the normal rectifier transmits current in one direction only, it is not suitable for supplying power to reversing mills, nor to any mill which should be quickly decelerated and stopped. Any additional equipment to permit regenerative braking adds so much to the cost of the rectifier as to make it noncompetitive with motor-generator.

In spite of these inherent limitations, the rectifiers were successfully and advantageously applies in several cases to supply power to mill drives.

The first installation designed in 1939 included two 3,500-kw units for the already existing hot strip mill of the Weirton Steel Company.[6] The mill drives were increased in size, and the rectifiers were added to the already installed three 3,000-kw motor-generators, providing a total of 16,000 kw on the 600-volt bus. Generators only are used for starting up the motors (which are never loaded when starting), and the rectifiers are then automatically connected to the bus. The voltage maintenance and the load division between the rectifiers and the generators are easily maintained by amplidyne regulators.

A merchant mill of the Kaiser Steel Company is driven by several d-c motors, rated from 300 to 1,500 horsepower. The power is supplied by a 2,500-kw, 600-volt rectifier. Phase control is used for starting the motors. Motor field control is used, as at Weirton, for adjusting the relative speeds of the several motors.

Two continuous tube mills are now under construction and each will be driven by a number of 600-volt d-c motors. The power will be provided by a 3,500-kw and a 1,500-kw rectifier, respectively.

Thus, the rectifier will, undoubtedly, find its legitimate, but limited, place in this field. It is doubtful whether it will replace largely the motor-generator for supplying power to the rolling mill drives.

Hot-Strip Mills

In no branch of the steel industry has the role of electric drive been so prominent as in the hot and cold strip mills. The rolling process made possible by these mills has revolutionized the industry to such an extent, and the process itself is, in turn, so dependent on electrical engineering that it deserves a discussion even in this brief review.

The metal fabricating industry is clamoring for more and more flat rolled steel, known in the trade as sheets, strip, and tinplate. Automobile bodies, freight cars, refrigerator cabinets, and other appliances, electric sheets, oil drums, and various containers, tin cans, and thousands of other applications, continuously growing in number, present their demands to the steel industry. In 1947 close to 29 per cent of all steel belonged to this class.

Twenty-five or more years ago a typical sheet mill, as shown in Figure 11, required a large amount of hard labor and the process was expensive. A sheet bar having dimensions of about, 8 by 3/8 by 24 inches, reheated in a furnace, would be passed several times through and over the rolls, requiring manual handling at either side by skillful operators. One or more reheatings would be needed before the sheet of proper width, length, and thickness would be obtained. Several sheet mills would be located side by side, as shown, driven at constant speed by an induction motor with a heavy flywheel.

A large amount of hand labor made the process expensive. Low tonnage output of then existing sheet mills could not keep up with the growing demand. The answer was provided by the development of strip mills.[7]

The art of rolling wide flat sheets, several hundred feet in length, has been developed within the last quarter century. The width of these sheets may vary from 30 to 96 inches. The finished thickness is usually between 1/16 inch and 1/8 inch. Such wide sheets of steel are delivered from a modern mill at a maximum speed of 2000–2200 feet per minute.

Figure 12 shows a typical layout of such mill. Starting from the top of the diagram, a heated slab, some 4-inches, 5-

Figure 14. Motor room of the hot strip mill

Three 7,000 kw motor - generators supplying power to d-c motors driving the finishing stands

inches, or 6-inches thick, passes through the roughing stands 1 to 4. These are so spaced that the same slab is never in more than one stand simultaneously. Thus, there is no need of providing a definite speed relationship between these roughing stands, and they are conventionally driven at a constant speed by either induction of synchronous motors. (In a few cases a reversing mill, similar to a plate mill, is used instead of the several roughing stands shown on Figure 12.) The slab emerges from the roughing stands elongated to 100–150 feet, reduced to a thickness of about 3/4 inch, more or less, and is then passed through a group of finishing stands, usually six in number. These stands are set on close centers, 18 to 20 feet, and quite obviously, the same sheet may be in all of these stands simultaneously. Thus, the rolling speed of each consecutive stand should be increased, as the thickness of the strip is reduced by the rolls. To provide for a wide variation of rolling schedules, calling for different thickness reductions or "drafts" on each stand, it is important to drive these stands individually by separate motors, with independent speed adjustment of each. Motors of 2,000 to 5,000 horsepower are usually employed to drive each stand.

In this case, again, the most economical and practical solution is the use of d-c motors, each with independent speed adjustment by field control (2-to-1 or more), supplied with power from several adjustable voltage generators.

The concentration of power at the finishing end of a large hot-strip mill is as high as anywhere in the industry, with the possible exception of some electrochemical processes. A mill illustrated in Figure 13, has a total of 27,000 horsepower of d-c motors supplied with power from 21,000 kw of 600-volt d-c generators. The problem of handling over 40,000-kw or close to 70,000 rated amperes of d-c power on a common bus is no mean task, considering the possibilities of fault current. Efficient as the electric machines are, it is not unusual to find that the total losses of motors, motor-generators, and auxiliary equipment, within a hot-strip mill motor room, are as high as 5,000 kw. To dissipate these losses and to keep the ambient temperature reasonably low the modern practice calls for a recirculating ventilating system. The hot air from the machines is discharged downward into the ducts in the basement, is passed through surface coolers (air-to-water heat exchangers), and is then pushed by fans into the motor room, through the machines, and so forth. Thus, the losses are "piped" away by water.[8]

The nature of the hot-strip load is cyclic. The speed of rolling is usually determined by metallurgical factors, and is usually higher than dictated by merely tonnage requirements of the mill. Thus, the slabs follow each other with certain time intervals between them. The mill load, starting with friction load (see Figure 14) gradually rises as the slab enters in succession the finishing stands. The peak load of, say, 30,000 kw or more will be reached in about ten seconds when all stands are full. After a brief interval of this maximum load, the latter gradually drops off again down to friction load.

The magnitude of this load and its cyclic character is apt to disturb the voltage regulation on the power system, even when the steel plant is tied with a large utility. Assume, for instance, that the d-c generators are driven by synchronous motors which operate with constant excitation. With the mill load changing from friction to over 30,000 kw, the reactive kilovars given out by the synchronous motors are going down by about 15,000 kva, which is opposite of what is needed for good voltage maintenance. Hence, the industry has adopted in the last ten years a practice of automatically controlling the excitation of these synchronous machines as function of their load. In addition to improving the system voltage regulation, this method by reducing the running light losses may easily save some 300,000–500,000 kilowatt-hours per year for a large strip mill.[9]

Many other refinements have been contributed by the electrical industry to the art of rolling strip.

The thickness of the hot strip should be checked while it emerges from the last stand at a speed of some 2,000 feet per second. Any measurement involving contact with the fast-moving hot metal is out of the question. An X-ray gauge has been developed for this purpose.

A suitably protected 100-kv X-ray tube is located under the moving strip. Part of the rays pass through the strip, another part through a selected "standard" of thickness. The comparison of the two values indicates to the operator any deviations from the standard.[10]

In many cases the moving strip should be sheared to uniform length as it comes off the mill. The length of cut may vary as much as two-to-one. A rotary type "flying shear," mounted at the finishing stand, is driven by separate motors. By changing the ratio of shear speed to that of the strip, the length of cut is adjusted. Once adjusted, it should be maintained with an accuracy of about 1/4 of one per cent. An electronic-amplidyne speed regulator is successfully doing this job.

Other problems of handling hot strip after mill delivers it, such as the operation of runout tables, coilers, and so forth, are also solved by electric means, but space does not permit going into this subject.[17]

It is obvious that from a practical viewpoint a modern hot strip mill could not be designed, built or operated successfully without electric drives. As a matter of fact, it is designed usually around the electric equipment. Thus, this type of mill which so materially reduced the cost of flat rolled steel, and made the quantity production of sheets for automobile and many other uses economically possible, owes its very existence to the electric equipment.

Figure 15. Typical load cycle of finishing stands of a large hot strip mill

Figure 16. Modern 5-stand tandem cold strip mill

Cold-Strip Mills

The Process. A still greater contribution to the steel industry was made by the electrical engineers in the field of cold rolling of steel after it has been delivered from the hot strip mill.

This strip steel, delivered in a coil form, is passed, first of all, through a so-called pickling line (acid bath) to remove the scale and other surface blemishes. Recoiled again, it is delivered to a tandem cold reduction mill.

A mill for rolling wide sheets may include three stands, reducing the strip in three passes from a thickness of 0.109 to 0.037 inch. A mill for producing tin plate may include five tandem stands, and will probably reduce a strip about 30-inches wide from a thickness of 0.072 to 0.010 inch, or thereabouts. The strip is wound up in coil form on a tension reel as it is delivered from the last mill stand.

When a limited tonnage, or a great diversity of products is needed, the cold reduction is economically done on a reversing cold mill. It consists of a single mill stand, with a winding reel at either side. By passing the strip back and forth through the mill, taking reduction for each pass, the strip is given the needed thickness. The reels, each driven by separate motors, alternate as a winding or an unwinding unit.

The strip is then passed through a cleaning line to remove oil picked up during the cold rolling. Wound in the coil form again, the strip is annealed in furnaces to remove the hardness created by cold rolling.

The next operation is to give the strip the proper finish and needed physical property; for this purpose the metal is passed through a "temper pass" or "skin pass" mill. The latter consists of one or two stands, with paying-out and winding tension reels. Very little reduction in thickness is given to metal on this mill, usually less than five per cent.

After this operation the strip is given the final processing, such as galvanizing, tin plating, and shearing.

The operating speed of cold strip mills has been raised in a spectacular manner within the past 20 years. In 1928 a tandem mill was built whereby the conventional speed of about 200 feet per minute was nearly doubled. In rapid succession the mill speeds were raised to 600, 800, and 1,000 feet per minute. In 1933 the first 5-stand tin plate mill was built with a top speed of 1,200 feet per minute. By 1938 several mills were operating close to 2,000 feet per minute. In 1941 the top speed of 3,800 feet per minute was reached. The war years have merely delayed the race, and it was resumed after the end of hostilities. Several tin plate mills were built, and some of these are in service, with a rated top speed close to 5,000 feet per minute. Finally, a 5-stand mill (discussed later) was designed and has been operating at a speed of 6,250 feet per minute, or 71 miles per hour.

This striving for higher speeds is, of course, based on economic factors. With substantially the same operating crew, a 5,000 feet per minute mill will probably produce double tonnage as compared with a 2,000 feet per minute mill. Even though the mechanical and electrical equipment is more expensive in the former case, the over-all operating cost per ton should be lower, everything else remaining constant. This is the industry's answer to the higher wages of steel mill workers.

Electric Equipment. Each stand of a cold strip mill and the tension reel are driven by separate d-c motors. The power is supplied from one or more generators. Generator voltage is used to speed up or slow down the mill as a unit. Motor field control is employed to readjust the relative speeds of the several stands, to take care of various rolling schedules.

For each new coil the mill is slowed down to a threading speed, in order to bring the strip through the several stands, to make a few wraps on the winding reel, and to make certain that the metal is under tension between the stands and at the reel. Then the entire mill is accelerated to its selected maximum speed, still maintaining substantially the same strip tension. If the latter condition is not met, the expected reductions of strip thickness will not be realized. The strip will be "off gauge." Furthermore, even with the same tension and the same setting of rolls ("drafts"), the gauge is apt to be different at high speed than it is at low speed. Hence, the logical desire of the operators to accelerate or to retard the mill as fast as possible, in order to reduce to the minimum the amount of "off gauge" material rolled.

These operating conditions impose rather severe requirements on the electric equipment. To accelerate several motors simultaneously while they are held together only by a relatively thin strip, to maintain their relative speeds during this period, to maintain also a fairly constant tension on the winding reel are a few of the problems faced by electrical engineers.

The first task is to suitably design the mill motors; that is to bring their inertias (WK^2) down and, at any rate, to match as nearly as possible the WK^2 of the several motors. This often means splitting the motor capacity at each stand into two or even four armatures.

For any given rolling schedule the motors may not be equally loaded so that the IR drops of their armature circuits may not equal. Thus, their relative speeds, if properly matched at low voltage, may not match at maximum speed and voltage, or vice versa. Suitable compensation for

IR drop must be provided in the control. An up-to-date arrangement is to provide a separate generator for each of the mill motors and for the reel, thus avoiding a common bus. In spite of this segregation the voltages of the several generators are quickly built up or are quickly reduced, maintaining the selected relationship.[11]

Figure 17 shows diagrammatically the arrangement of the high-speed tin-plate mill which has been operated at speeds in excess of 6,000 feet per minute. The ratings of the several motors are indicated on the sketch. The total installed capacity of the drives is 16,850 horsepower, backed-up by 14,200 kw of generators, mounted on two sets. Each mill and reel drive has its own generator.

The 1,750 and 3,500 horsepower drives are direct connected to stands 1 and 2, respectively, through a set of pinions. In other words, the motors run at the same speed as the rolls. The 3,500 horsepower motor is built as a double armature machine. The drives for the stands 3, 4, and 5 are built as twin drives, that is, the top and bottom working rolls are driven by separate motors, tied together by electrical means only. Thus, the conventional mill pinions are eliminated. To reduce the stored energy of rotating masses it was found advantageous to run the motors at a lower speed than the rolls. Step-up gears are employed between each motor and the respective roll. The presence of such gears also permitted the location of the motors on suitable centers. For the stand 5, each of the twin motors is built with two armatures on the same shaft, in order to keep the total moment of inertia still lower.

To operate these several motors and mill stands in unison, without tearing the thin strip apart and without affecting its gauge, obviously requires a carefully laid out control system. The heart of the latter is, again, the high-speed rotating amplifier and regulator, known as the amplidyne. A number of these amplidynes are used for building up or maintaining the voltages of the several generators in the selected relationship, for dividing properly the loads between the twin motors, for maintaining constant strip tension on the winding reel and for several other purposes. It can be said that in case of a modern cold strip mill the electric equipment acts as the "brains and brawn" of the process. Without the electric equipment the process itself would not be feasible.

Since the strip is under tension during rolling, it is important to give the operators some ready means of measuring and indicating this value. Here, again, electric means are provided with good effect.

A spring-mounted roller is located between the adjacent mill stands, or between the last stand and the winding reel. The roller deflects the strip slightly upward (2–3 inches) from the pass line. The higher is the strip tension, the stronger is the downward push on the roller against the supporting springs. The latter are rather stiff, permitting a maximum vertical travel of about 1/8 inch. This travel is proportional to the strip tension. By measuring this travel by well-known electromagnetic means, such as used in electric gauges, the strip tension can be readily indicated by electric instruments. In this manner the mill operators are always fully aware of the pull exerted on the strip.[13]

Auxiliary Drives

The rolling mill drives are not the only motor applications in the steel industry. As a matter of fact, their over-all installed capacity, great as it is, is less than half of the grand total of motors in the steel industry.

Motors for pumps, compressors, and fans, of which a steel plant needs quite a few, are not much different from similar motors in other industries. The same applies to motors in coal preparation plants, coke oven by-product plants, and like. A-c motors are usually employed.

Blast furnace blowers are, as a rule, steam turbine driven. They are usually located next to the source of waste gas and to the power plant. Automatic control of blast is required, which usually means speed adjustment. Thus, the use of steam drive is logical, instead of conversion of steam to electric power, and then again to mechanical power at the blower shaft.

Bessemer blowers may be in a different category since they are often located remote from the powerhouse. A number of these blowers are electrically driven. Slip ring motors with secondary control were originally employed to provide speed adjustment. Some of the recent blowers were designed with mechanical means of controlling the air volume. Constant speed drives become feasible, making it a very good application for synchronous motors rated about 4,000–6,000 horsepower.

The most specific motor applications in steel mills are the so-called auxiliary drives usually employed for handling metal during and between the various processes. Mill screwdowns, mill tables, manipulators, and transfer cars, as well as cranes, are examples of this class.

Since the early days of electrification the steel industry has chosen the heavy duty d-c motor for this application. The

Figure 17 (left). Layout of a tandem mill rolling cold strip at speeds up to 6,000 feet per minute

Figure 18. Motor room of the high-speed cold mill shown on Figure 17

Figure 19. Heavy duty d-c motor used for mill auxiliary drives and cranes

inherently better motor characteristics and superior control as compared with a-c drives were the basis of this choice. These factors remain as strong today as they were 50 years ago.

Since 1926 the Association of Iron and Steel Engineers standardized on ten motor ratings arranged in logical steps from 5 to 150 horsepower. For one given rating there is only one rated speed. Series, compound, and shunt motors were available, all ratings based on 230/250-volt power supply. Mounting dimensions were standardized so that complete motors of the same rating, regardless of make, could be interchangeable.

In 1947 the Association adopted a new standard, which maintains the same mounting dimensions but provides for each motor frame size the next larger rating, as compared with the 1926 standard. This has been obtained by better utilization of available space, without permitting any higher operating temperature, nor sacrificing the motor ability to handle high peak loads.

While the popularity of d-c motors persists, and even grows, the method of supplying power to them is undergoing a marked change.

The previous universal practice was to provide a constant potential bus supplied with power from 250-volt motor-generators. The 1,000 and 1,500 kw units were most common. These sets were located at strategic points in the steel plant. The d-c motors were conventionally equipped with magnetic control. The growing tendency is to provide many auxiliary drives with separate generators and to employ the generator voltage or Ward Leonard control. For instance, every new blooming or slabbing built in the last 12 years has been equipped with Ward Leonard control for its principal auxiliaries: reversing front and rear tables, right and left side guards, screwdowns, and bloom shear. Each of these drives usually employs one or two motors of 150–250 horsepower capacity and a separate generator of suitable capacity. Such applications as flying shears, runout tables, strip coilers to name a few, also fall in this class. The several generators are assembled customarily together in groups of four or even six and are driven by a common synchronous motor.

The advantages of this system are many. Heavy reversing and accelerating contactors in the armature circuit are replaced by small devices handling merely the generator field. Smoother, yet faster, acceleration of the drives is possible. The 230-volt mill motors can be readily operated at double voltage, thus permitting higher output per frame and higher maximum operating speed. Thus, lower electrical and mechanical maintenance and superior performance are realized.[13]

The adjustable voltage systems have found a very fertile field in the numerous processing lines, such as pickling, cleaning, galvanizing, and shearing, which are encountered in any cold strip mill plant.

This tendency toward the greater use of Ward Leonard control reduces the load on the 250-volt d-c bus and transfers it to the a-c power system. At the same time the advantages of d-c motor drives are maintained and are even enhanced.

One should not conclude that the constant potential 250-volt d-c power supply in steel mills will disappear. There are too many drives, such as numerous cranes and auxiliaries, where Ward Leonard control is not economically feasible, nor is even needed. Therefore, the need of a-c to d-c converting units operating at constant d-c voltage will be always present in a steel mill.

The development of single anode ignitron rectifiers which gives a low arc drop and, therefore, good efficiency even at 250 volts, has challenged the monopoly previously held by the motor-generators. The steel industry has, in effect, adopted the arc rectifier in ratings of 1,000 and 1,500 kw as a preferred equipment for this purpose.

Electric Heating

There are two main applications of electric heat in the steel industry, arc

Figure 20 (left). General view of typical strip processing line

Individual d-c motor drives with Ward Leonard control are used. This line is used for trimming and shearing

Figure 21. Continuous electric furnace for heat treatment of silicon and stainless steel strip

furnaces for melting metal, and resistor and induction furnaces for heat treatment. Since the cost of electric heat is higher, on the mere thermal basis, than that of other fuels, its use is competitively justified when other savings like reduction of rejects or higher quality of product can be realized. There are many such applications.

Arc Furnaces

Electric steel, melted and refined in these furnaces, is considered to be of higher and more uniform quality than the commercial grades. An electric furnace, being on the average smaller than an open hearth furnace, lends itself better to production of smaller lots or "heats" of special steels. Hence, it is employed mainly for the making of the more expensive steel alloys.

The demand for these alloys and the tonnage of electric steel rise together. The annual capacity of electric furnaces in 1935 was 1,050,000 tons. Just before the World War II it rose to 1,500,000 tons. In 1945 it was close to 5,500,000 tons. This spectacular rise was primarily due to the intensive use of high tensile strength and other special alloy steels in war production. Some of this arc furnace capacity is not fully utilized in postwar steel production.

Electric arc furnaces had been built in capacities as large as 100 tons, although a 35–50 ton unit is more representative of the large furnace class. An average American ingot-producing furnace gives about 35,000 tons annually. A good average value of power consumption is about 600 kilowatt hours per ton.

The primary side of the furnace transformer is usually connected to the high-voltage system of the steel plant, up to 34.5 kv. No-load taps and wye-delta connections on the transfer primary winding are customary.

The most interesting innovation in electric equipment for furnaces is the introduction of rotating regulators for the electrode drives. A d-c motor is used for each electrode. It is supplied with power from a separate amplidyne generator (or equivalent). The signals from the electrode current and voltage control the amplidyne fields and cause the motor to function suitably. This type of control has proved to be accurate, fast, and yet stable and smooth.[14]

Resistor and Induction Furnaces

The percentage of steel-mill heat-treating furnaces employing electric heat is not very high. However, many notable installations were made where precision quality control or other inherent advantages of electric furnaces were of most importance. A few examples will illustrate this point.

Figure 21 shows a 450-kw furnace for heat treatment of silicon and stainless strip steel at temperatures as high as 2,000 degrees Fahrenheit. In this case the strip speed is rather low, less than 10 feet per minute. Two continuous strip processing lines are being built, each to include a 2,000 kw resistor furnace as a component part, and speeds up to 200 feet per minute are provided. On another and slower processing line for heavier strip, the latter passes through an induction coil energized by two 700-kw, 9600-cycle generators, and is heated to a temperature of about 1,300–1,400 degrees Fahrenheit.

During the wartime shortage of tin the steel industry had to change the method of applying tin coating to tinplate from the hot-dip to electroplating process. The coating is applied to a strip moving at a speed up to 1,000–1,200 feet per minute. Plating currents up to 60,000 amperes at nine–ten volts are provided either by generators or dry-plate rectifiers.[15]

The electroplating tinning saves better than 50 per cent of tin as compared with the hot-dip method. However, the finish is not as bright as desired. A so-called "flowbrightening" process is, therefore, added to the processing line immediately following the tin-plating. The idea is to heat the coat of tin moderately, causing the tin to "flow" and to give thereby a smoother finish. Electric heat has been successfully applied for this purpose in two different manners.

Under the first method 60-cycle alternating current is carried by the portion of the strip to be heated. Practically 100 per cent conversion to heat is realized. Current collection problem has been satisfactorily solved.

The second method consists of using high frequency for heating the moving strip. Radio frequency of over 200 megacycles has been used on several installations. Since the strip moves at high speed, it becomes necessary to concentrate huge blocks of power in the high frequency transmitters, up to 1,000–1,200 kw on a single processing line.[16] It is claimed rightly that more radio frequency capacity has been installed for this purpose in the steel industry than is used in all broadcasting stations put together. These equipments are performing very satisfactorily even though they are rather expensive. Tests were also made, with very good results, to apply for this purpose induction heat of lower frequency, like 9,600 cycles. This will very materially reduce the first cost of the installation.

Conclusion

The partnership of electricity and steel has been quite fruitful. Electric power has contributed a large share toward economical mass production of steel, on which our entire industrial life is based. If the last quarter of a century is any criterion, we should expect that in the next 25 years the art of steel making will be allied still closer to electrical engineering.

Trends in Electron Tube Design

W. C. WHITE
FELLOW AIEE

THOMAS A. EDISON, John A. Fleming, Lee DeForest, and the other pioneers in the development of the electron tube found it necessary, of course, to do much design work, but quantity production of many thousands of tubes to meet a specification for use in standardized pieces of equipment appears to have been first encountered by the French in the early part of World War I. When the military communication needs arose at that time and the decision was made to adopt small electron tubes, it was natural for them to turn to the manufacturers of incandescent lamps for production requirements (Figure 1). These lamp makers under the stress of war utilized wherever possible parts and techniques of lamp manufacture. These techniques persisted for many years in tube design and a few features of lamp design still are retained. Many tube manufacturers today are also makers of lamps.

Tube designers and their associates have always been a restless, resourceful group constantly adding new types and forever changing materials, designs, and processes in an effort to expand still further the field of usefulness of tubes; to lower their cost and to improve their quality as well as performance. This fact must be kept in mind because by the time this paper is presented, some statements herein already may be out of date.

During the more than 30 years that tubes have been designed on an engineering basis and manufactured in quantity, there have been innumerable changes in tube design. It is not within the scope of this paper to trace this history but rather to review briefly a number of the present broad design features of electron tubes and, in particular, to describe trends that designers are thinking and worrying about and thus give clues as to what changes may become increasingly apparent in the next few years.

There are a number of ways in which such a study might be arranged. It seemed best to divide up the broad subject of tube design into a number of subdivisions based on certain fields of tube applications. In doing this, however, it must be kept in mind that the term "electron tube" is now a broad descriptive term. Their size and weight range from a unit that could easily go astray in a vest pocket to one requiring the aid of a crane in moving it about the factory (Figure 2). Also, there is little in common, except tightness, between a sealed steel-envelope ignitron and a glass radio-receiving tube. Therefore, from the viewpoint of an engineer specializing in one particular class of electron tube, this paper well may be meager in its coverage, but it is hoped that it will give engineers who look at tubes fundamentally as useful tools in electrical engineering a picture of where and how this science is changing and progressing.

General

In any study of tube design, the enormous continuing expansion of new and different types of tubes and their application must be kept in mind. It cannot be expected that a tube suitable, for instance, for the control of an electric blanket can be used in an intricate computing instrument even if the current and voltage relations are similar. There also will be a growing number of unusual and highly specialized devices utilizing the flow of electrons or positive ions. Examples are the Geiger counter, television camera tubes, electron microscopes, betatrons, and electron diffraction instruments. This paper will not even attempt to list all of these special devices but will discuss only trends in the broad classes of tubes which find wide usage. In general, only trends in the Americas will be included. Each of the various fields of application of electron tubes places a different emphasis on the many design factors involved. For some special applications, even a small tube may cost $100 or more and yet its use be highly justified. On the other hand, a tube selling at such a figure, no matter what its capabilities, could not possibly be considered for a home broadcast receiver.

As in any new engineering development, there are differences of engineering opinion on certain aspects of a subject. Time, as usual, will resolve these technical controversies and the various factors will be fitted into their proper place.

Ever since the science of nucleonics has become a common subject of discussion, suggestions have been made that materials giving off alpha, beta, or gamma particles now available after irradiation in an atomic energy pile should find usefulness inside electron tubes. To date no such application has been disclosed and it would appear that more knowledge and research are necessary before this new science will be directly helpful to the tube engineer.

Broad Trends

In the early construction of electron tubes, all of the electrodes were made of pure metals. The science now has progressed to the point where this is no longer true and in nearly all cases the electrodes have a special surface coating over a base metal in order to provide a maximum usefulness.

Electronics continues to be a science of extremes. Tubes commonly are employed throughout the frequency range between 25 cycles and 30 billion cycles per second. As has been noted, there are enormous differences in size. Tubes are available that will detect a current of 10^{-16} amperes or deliver a peak current of

Paper 48-129, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–5, 1948. Manuscript submitted February 11, 1948; made available for printing March 15, 1948.

W. C. White is with the research laboratory of the General Electric Company, Schenectady, N. Y.

Figure 1. The French World War I all-purpose radio tube; manufactured on a production basis in 1916

10^4 amperes. In a similar way, tubes will respond to potentials of a few microvolts and yet the modern betatron deals with a hundred million volts.

Another interesting feature is that the engineer in no other highly specialized field utilizes regularly so many of the chemical elements including several of the rare ones. More than 30 of the elements commonly are employed by the tube engineer and they span the alphabet from argon to xenon and zirconium.

The frequencies at which tubes are operated are not a factor in their design in the low end of the spectrum of electromagnetic radiations. As the frequency increases, its importance in connection with the design of the tube increases. In the range around 100 megacycles, it has become such an important factor that part of the tube must be considered a part of the circuit. This becomes increasingly true as the frequency is increased still further into the microwave region where the tube structure is often also the circuit.

Another trend apparent during the past few years is that most of the new outstanding advances in electronics have taken advantage of our increasing knowledge of electron beams or what is termed the science of electron optics. Examples of this are the betatron,[1] phasitron,[2] radial beam tubes,[3] cyclophon,[4] traveling-wave tubes,[5] television camera tubes,[6] (Figure 3), memory tubes,[7] and others.[8–10] The author believes that this trend will be accelerated and it may well be that almost all of the really new and worthwhile advances from now on will be the result of our increased understanding and application of electron optics. Young engineers studying for or just entering the field

Figure 2. A high-voltage high-power sealed ignitron used for power conversion

Rated for 150 amperes at 20-kv inverse voltage

of electronics as well as laboratory groups, well might keep this in mind. The number of engineers and physicists with a thorough knowledge of this branch of science plus the other factors needed for successful research and development are entirely inadequate to the possibilities that exist.

Radio-Receiving Tubes

Miniatures and Subminiatures

Engineers in this field in visiting one another do not delay very long before they are discussing miniatures and subminiatures. From the days of the "peanut" tube of World War I the desire for smaller sizes of tubes has existed but it has taken time to solve the problems of maintaining quality and performance without additional cost. How far the trend towards ever smaller sizes is going is anyone's guess. Press releases from a United States government laboratory of late have described tubes of the "grain of rice" size.[11]

Both the tube and receiver manufacturers have good reasons for wanting smaller tubes. The tube manufacturers see this trend as a basic way toward lower costs because less material is involved and it should be possible to keep the other cost items at about the same or even lower level. Additional advantages are possibilities of speeding up certain manufacturing processes and the minimizing of space requirements for packaged tubes all the way from factory warehousing to the dealers' shelves.

The manufacturers of receivers are working constantly toward a lower cost for their product and smaller tubes mean smaller chassis and cabinet dimensions with accompanying savings in material. In addition there are sales appeal features and fewer problems from microphonics, less breakage in handling and shipment, and better high-frequency performance.

Miniatures[12] have been available for nine years or more but originally were designed and utilized almost entirely in battery-operated portable radio receivers and other devices having the same general requirements.

Most miniature tubes are built with tubular bulbs, the trade designation for which bulb is *T* followed by a numeral which is the diameter of the bulb in eighths of an inch. This is not to be confused with the assigned group of designations such as *6T8* and *12AT7* where the *T8* and *T7* have no significance as regards the bulb diameter.

Most receiving tube engineers classify tubes with *T5* to *T6*$^1/_2$ bulbs as miniatures with a further general understanding that such tubes have basic electrode structures not greatly different in size from similar standard larger tubes (Figure 4). The reduction in dimensions of miniatures is accomplished largely by the elimination of wasted space and unnecessary parts from similar large tube designs. This is indicated in Figure 5 where a modern miniature of a World War II development is shown to be small enough to slip inside the hollow stem of a tube built during World War I. The smaller tube has superior characteristics, however.

Subminiatures have diameters below a *T5* bulb and some go down to as small as *T1*$^1/_2$ bulb (Figures 6 and 7). At present subminiatures are used almost exclusively in special applications such as hearing aids, very small portable receivers and certain military applications where space and weight requirements are extreme.

World War II military requirements were powerful influences in the development of subminiatures, the best example being the tubes used in vast quantities in connection with the proximity fuse.[13]

Another factor accelerating the trend to smaller dimensions is the use of tubes in relatively large numbers for accomplishing a desired result and, therefore, the space occupied by the tubes becomes important. Examples of this are modern electronic computers which may employ several thousand tubes as well as television receivers having several dozen.

In spite of the size of miniatures, the practice of including several electrode structures in one bulb continues. As an example, there is now available inside one miniature sized bulb the combination of three diodes and a triode.

Some subminiature tubes have flattened bulbs. In general this is believed to be desirable only for some special application such as hearing aids. Most makers of tubes look askance at bulb structures that are not symmetrical around a vertical axis. This is due to the fact that so much of their automatic manufacturing equipment is predicated on this fundamental geometrical feature.

Miniature tubes are not applicable for all positions in modern radio receivers because the necessary heat dissipation for some design requirements is excessive for these small bulb sizes.

Seven- and 9-pin moulded glass headers are standard for miniatures in the industry. For many sub-miniatures, wire leads are substituted for pins.

MISCELLANEOUS

For applications in battery-operated equipment, filament power is down to 50 milliamperes or less from a $1^1/_2$ volt dry cell. For some special uses, tubes having even lower filament currents are available.

In radio receivers, pentodes still are generally used for radio-frequency and superheterodyne intermediate frequency amplifiers and pentagrid tubes are employed almost universally, as converters.

There are now about 500 types of receiving tubes listed, and of these more than 50 are miniatures. There seems to be no question but that the number of types is going to increase at an accelerated pace due to the requirements and developments in television and frequency-modulation broadcasting, as well as other special uses.

The demand for higher values of transconductance which has confronted the tube designer from the beginning continues, and associated with it is the accompanying need for lower output impedance values in order to give more uniform response over a broadband of frequency. As a result, the tube designer has been forced to much closer interelectrode spacings, particularly between cathode and grid where three mils or even less is now common. As has been indicated, standard sized tubes still are used for some functions in receivers where the heat dissipation is too high for the smaller sized bulbs of the miniatures. Examples of this are rectifier tubes for large receivers and tubes for deflection of the beam in picture tubes as well as for certain audio-amplifier circuits.

In many standard sized receiving types, the steel envelope design continues in common use. New designs of receiving tubes are relatively infrequent in the large standard size, so probably there will be few new designs of the larger metal tubes in the near future.

Some Manufacturing Features

The use of coated filaments applied in the form of the carbonates of the alkaline earth metals is almost universal.

Grid wires commonly employ molybdenum or its alloys. Such wires are used in diameters as low as one to two mils. The minimizing of primary emission from the grids is usually accomplished by some special surface treatment, each manufacturer having his own favorite technique.

The anodes are mostly of iron or steel with some surface treatment. A new material, proposed for this use, is aluminum-coated steel. This is built into the tube as a bright surfaced metal but upon being raised to a bright red heat during evacuation of the tube, it suddenly changes to a dark gray color. This is a very useful characteristic as it permits the freeing of the anode metal from gas with reasonable amounts of heating power due to the poor radiation of a shiny surface. In the finished tube, however, it provides a dark and thus high heat radiating surface permitting lower anode temperatures. The basic idea seems to have come from the Germans and is one of the two worthwhile new ideas that were initiated in enemy countries during World War II. The other is ceramic material suitable for tube seals and envelopes. Although this latter is an important new development on which tube engineers are very active in the United States, as mentioned elsewhere, it is not being applied as yet to receiving tubes.

Barium-content getters are almost universally employed. Zirconium, although in fairly common use for transmitting tubes, is not being applied commercially to receiving tube production.

Figure 3 (left). Image multiplier Orthicon as used in television cameras for outside pick-up

Figure 4. The miniature tube (at right) has an electrode structure nearly as large as a standard sized tube

The smaller size is accomplished mostly by eliminating unnecessary parts and space

Figure 5. A World War II tube slips easily inside the stem of one built during World War I, yet the smaller one shows better performance

Most receiving tubes are designed for operation of the cathodes at 6.3 or 12.6 volts although there are many other voltages utilized for special cases. Tubes designed for 110-volt heater operation would be welcomed by many receiver designers but several difficult problems are involved and this feature is not particularly favored by tube engineers and, except in very special cases, probably will not be used to any great extent.

Most radio receiving tubes are operated at plate voltages under 150 and a common maximum rating is about 300.

Ever-Present Problems

The tube designer constantly is confronted with the problem of cutting tenths or even one-hundredths of a cent out of the cost of a tube. This is accomplished either by redesign or lower manufacturing losses. The mechanization of tube manufacture is an important phase of cost reduction. It is going on actively step-by-step in all the operations involved. Complete machine assembly of tubes on a commercial basis still appears to be a future development.

Two other problems confronting tube engineers is the minimizing of grid emission and the decrease and control of electrical leakage between the heater and the cathode in tubes utilizing these features. The latter problem is a most difficult one because of the problem of designing a hollow red-hot metallic conductor about the diameter of the lead in a pencil into which is put another red-hot conductor with only two mils available for space in which to place insulating material, the whole having to operate in the reducing action of a high vacuum. This combination must be operated not only at 110 volts between the two elements without breakdowu, but the leakage resistance between the two must be above about 100 megohms per inch of conductor. Admittedly, this is quite a problem, particularly in devices which must be manufactured for a fraction of a dollar each in million lots. Tube designers are meeting this very difficult requirement by the use of alumina. Many close manufacturing controls are involved, however.

As discussed elsewhere, there is a constant urge to minimize early life failures and this can be done only by careful attention to scores of design, process, and material details. A companion problem is convincing receiver designers that tubes should be operated conservatively to minimize early failure and in some cases to obtain long average life.

Another favorite topic for discussion is when or when not to create a new type of tube to meet the real or fancied demand of someone with a new circuit or application. Most tube engineers would consider this a short and sketchy recitation of their many problems, but it at least gives engineers in other fields an idea of what some of the problems are.

New Problems

The tubes available for radio receiver designs are suitable in general for frequencies up to 216 megacycles, which is the top limit for present commercial television. However, tubes for the citizens' radio band (460-470 megacycles) and the wide frequency zone extending up to nearly 1,000 megacycles that has been set aside for color and other improved television systems presents a whole new series of problems. For these higher frequencies, some of the special tubes, such as klystrons, disk-seal tubes, and dyotrons, to be described later, may well enter the picture.

Future Problems

In discussing the future with men in the industry, a number of subjects are usually introduced. One is a need for a special tube for frequency-modulator receivers to combine the functions of discriminator and limiter and possibly include other useful characteristics. As

Figure 6. Sizes of subminiature tubes compared to a standard length cigarette and kitchen match

Figure 7. Comparison between T-1 and ST-12 types for size and simplicity of design

one engineer expressed it: "We know that someone is going to pull such a tube out of the hat, but we don't know from whose hat it is coming."

Although ceramics are not employed today in standard receiving tubes, this technique is being thought about as one possible way of building miniatures that will dissipate more power. There are reports that such tubes have been built in Germany and are operated at a temperature of several hundred degrees.

There is also some speculation on the substitution of tubes soldered into their circuits rather than utilizing bases and sockets. There are a number of factors favorable to such a future development. Some of these are the new printed circuits and the wire leads on subminiature tubes. There is also the fact that there is less tinkering nowadays with radio receivers in the home either by amateurs or professionals. The diagnosis and repair of faults in a modern radio receiver can best, and sometimes only, be accomplished in a well-equipped radio service shop. The advent of television receivers emphasizes this trend. It is also no easy matter for the designer of a television receiver to arrange for chassis units in which every one of the two dozen or more tubes easily can be removed and replaced, even with bases and sockets.

Small Receiving Type Tubes for Industrial Control and Instrumentation

For many years this field of application was supplied by using standard radio receiving tubes. In order to obtain from them the greater uniformity and longer tube life needed, it was customary to operate the tubes very conservatively as to plate voltage, plate current, and often cathode temperature. It also was believed that the low cost of receiving tubes and their almost universal availability were strong reasons for following this policy. Of late, however, opinions on this subject have been changing. This is attributable to a number of factors.

1. Even under favorable conditions, the life is often too short for use continuously 24 hours per day. Industrial users of tubes now talk about the life in years rather than in a few thousand hours and the elimination of early failures is of increasing importance.

2. Mechanically, some users (often mistakenly) believe that radio receiving tubes are not strong enough for their applications. They need not have the extreme sturdiness of the tubes used in proximity fuses[13] which were actually shot out of a gun, but they may incorporate to advantage some special mechanical design features for some of the new services.

3. Users of tubes for instrumentation in particular have been critical of the wide variation of electron current and other characteristics between individual tubes.

4. Many tubes have not been considered satisfactory as regards constancy of anode current during life.

5. The great increase in the extent and variation in industrial use has created new requirements.

6. From time to time a tube manufacturer has changed some electrical or mechanical design feature which has been unimportant from the viewpoint of radio receiver use but has introduced serious difficulties in certain industrial applications. Therefore, revised and more definite specifications may be looked for in the future.

A good example of this last factor was a time delay relay, the coil of which was operated from the plate current of a receiving type tube. The current and voltage requirements were very low and, as very long life was desired, the tubes were operated at subnormal cathode temperature. Satisfactory results were obtained with renewal tubes for a number of years but during the war apparently new cathode materials were substituted or a process changed so that, while the electron emis-

Figure 8. The mortality curve of vacuum tubes assumes a shape shown in B as design and quality are improved

sion was normal at rated heater voltage, it was entirely inadequate at the lowered heater temperature used in this industrial application. Therefore, renewal tubes of the later date of manufacture were inoperable in the equipment in question.

One manufacturer has announced a new line of small industrial tubes to replace similar radio receiving tubes. Initially there are three types in this line (not miniatures). Two of these are of glass and one has a metal envelope. These three new tubes are in general mechanically and electrically interchangeable with corresponding radio receiving tubes. They, of course, have different designations and incorporate improvements over their radio counterparts as to life, uniformity, constancy of characteristic during life and mechanical strength. This feature will allow users of these tubes in industrial equipment to decide the merits of such specialized designs for their own particular devices and operating conditions. The use of this specialized line of tubes for industrial applications as described will be watched with great interest both by the tube makers and manufacturers of industrial electronic equipment.

That this general subject is an important one and of considerable interest to the members of the Institute is evidenced by the fact that the AIEE joint subcommittee on electronic instruments prepared a questionnaire on the subject of tubes in this field, and in response obtained a wealth of information. This was summarized, presented, and discussed at a 2-day meeting sponsored by this committee in Philadelphia during March 1948.

Tube Life

Of all the tube characteristics of interest to industrial users, life[14] is probably the most important. There are a number of features in connection with tube life that are of interest.

If the operating life of a tube were dependent on a pure random phenomenon, then a plot between the percentage of the tubes still operating and hours of operation would look like curve *A* in Figure 8. In such a case, taking a tube out of service, for instance, at 1,000 hours and substituting a new one as a method to insure continuity of operation is illogical. The reason, of course, is that at the end of 1,000 hours any given tube is as likely to operate another 1,000 hours as a renewal tube is to operate its first 1,000 hours.

When the life of a tube is based on some definite physical effect, such as evaporation and burnout of a pure tungsten filament, then the life expectancy curve tends to assume a shape, such as shown in curve *B*. The more definitely the end of life is associated with a single definite variable and the better the manufacturing control in the making of the tube, the more pronounced will be the shape of this curve.

The upper left portion of these curves is the important region. This is due to the fact that prematurely early failures are particularly troublesome to the users and, therefore, considered undesirable by tube manufacturers. To a large extent these early failures are due to accidents rather than to any basic factor controlling life. The average life of many modern radio receiving tubes, however, is satisfactory for some industrial uses.

There appear to be two ways of meeting this situation and both are being employed. The first is the introduction of continual improvements in manufacturing control and testing so as to eliminate before shipment the tubes that will show early failure. The second method is to provide increased design life and further

Figure 9. Microwave reflex oscillator tube

This general design suitable for frequencies up to 10,000 megacycles

Figure 10. Traveling-wave tube having high gain and very broadband characteristics in the 4,000-megacycle region

insure longer life by conservative operation and provide improved conditions of voltage constancy and a minimum of off-on interruptions. By this method the abscissa scale of Figure 8 is extended to such an extent that the critical right upper portion of the curve tends to become flatter for any definite number of hours.

Small Tubes for the Telephone System

Many of the engineering requirements fundamental in this application of electron tubes are quite different from those of radio broadcasting. For the most part, the tubes are of low power and superficially many appear to be similar to radio receiving tubes although they differ to a marked extent in ability to meet certain basic requirements.

The frequency range of tubes is just as extreme as in radio broadcasting, running all the way from 60-cycle, low-power rectifiers[15] to 4,000-megacycles and above as used for microwave relaying stations.[16]

In the voice and carrier frequency field, uniformity of characteristic, constancy of performance during life, and a long average life free from early failures are all important requirements. Transcontinental lines, particularly if carrier is involved, require a simultaneous use of many hundreds of tubes. This emphasizes the need for life reliability in each individual tube. To gain this end, a long-life design is the first requirement; and this is supplemented by continuous operation and carefully controlled operating conditions such as constancy of cathode heater voltage. In such applications it is also customary to check the tube performance periodically and eliminate tubes in which a slight falling-off of performance is noted. It is sound economically in the telephone system to employ a higher cost for certain tubes in order to obtain better performance and life because of the economies effected elsewhere in the system.

Miniature tubes are of interest for mobile equipment, in satellite installations where the complete equipment is mounted in a small case, sometimes on a pole installation, and where the power supply of filament and plate may be supplied over the incoming lines.

There is not a great deal of interest in steel-envelope tubes except for special cases where the metal envelope of itself is highly desirable. A good example is the single-cavity reflex oscillator tube. A movable metal diaphragm for tuning is a necessary part of the design (Figure 9).[17]

For certain types of equipment, it has been found advantageous to mount the tubes permanently into a chassis and substitute soldered connections to the tube terminals for the usual base and socket arrangement. The completed assembly is treated as a packaged unit, removable as a whole, for inspection, maintenance, or repair. A "permanent" tube designed to be incorporated inside a cable has been reported and in such cases, of course, the tube life must match the estimated useful life of the cable.

At the present time there is much interest in tubes for use in the 4,000-megacycle region which has been assigned by the Federal Communications Commission for microwave beam relaying. The velocity-modulation type of tube, of which the klystron is an example, now is used in the Boston–New York microwave relay link. Showing promise for future installations is the traveling-wave tube (Figure 10) due to its high gain and broad-band characteristics, and the disk-seal triode for its low noise and satisfactory broad-band features. In the highly refined designs of these special microwave tubes, close cathode to grid spacings, fine grid wire diameters, and a smooth surface for the electrode structures are carried to extreme values.

Figure 11. A television picture tube with a 10-inch diameter face

In the case of small thyratrons, there is not the marked trend toward gas filling evident in the industrial field. Inert gas filling is used frequently but only as an addition to and not as a substitute for mercury vapor. This is a logical combination because extreme temperature variations are not often encountered in this field, the anode voltages are low and the tubes run practically continuously.

Television Picture Tubes

Up until recently engineers in this field were most active on the development of projection-type tubes to provide larger pictures than those obtainable directly on the face of the tube. Although there is still activity on this subject, it is not occupying in general as prominent a part in development programs as it did a year ago. This is due probably to the fact that television commercially seems to have "turned the corner" finally. Therefore, all possible effort is being placed on lowering the cost and improving the performance of direct view cathode-ray tubes for television reception. Projection tubes as now used give a picture none too favorable in sharpness and brilliancy when compared with the most modern larger direct view tubes.

There seems to be a growing opinion that until the resolution of the picture is improved increasing its size is only beneficial when it is viewed from a greater distance and is, therefore, chiefly applicable to larger groups of people than normally gather in the average home.

The opinion also is expressed that the projection tube is not now the key factor in the problem of larger pictures by projection. The real problem appears to be a satisfactory low cost optical system to supplement the tube.

Of considerable interest in the industry today is a discussion of two active developments, namely, the matter of alumi-

num-backed screens and ion traps. Many factors are involved. The aluminum-backed screen, the newer feature of these two, has a deposit of very thin aluminum on top of the fluorescent material in the bulb interior. The proponents for this development are enthusiastic about the brighter image obtained, the improved contrast and definition of the picture, and the prevention of the formation of the troublesome ion spot.

The ion trap is a tube design feature aimed to solve in a practical way the problem of the ion spot. This ion spot is a circular spot or area of darkening discoloration on the face of the tube that slowly and increasingly shows up during tube life. It has been found to be caused by the negative ions produced from the electron beam. The ion trap is an ingenious arrangement by which a magnetic field is made to deflect the negative ions into a different path than the electrons on somewhat the same principle as employed in the mass spectrometer. Advocates of the ion trap believe that it is the surest way of eliminating this troublesome effect and at the same time give the lowest tube cost for a satisfactory picture.

The life of direct view cathode-ray tubes as used in television in general has been very satisfactory as is the color of the phosphor and its persistence. Unlike the field of radio receiving tubes, there probably will not be as large or as rapidly growing number of types of picture tubes at least in regard to the bulb dimensions. This is due to the fact that in order to obtain low-cost bulbs the manufacturer must expend very large sums in tooling up for their production.

There is a thorough standardization system similar to receiving tubes set up among manufacturers as regards interchangeability on a given type designation. The present standard enjoying the largest production is a 10-inch diameter tube. However, there appears to be a trend to 12-inch tubes and possibly larger ones if they can be produced at only slightly higher cost than the 10-inch size (Figure 11). Tubes having a face diameter of 20 inches are now commercially available. The matter of rectangular-faced bulbs is receiving some consideration for production.

The beam in a cathode-ray tube may be focussed either by a magnetic or an electric field. The same is true of the deflection of the beam. Many factors are involved in the choice made of these methods. Today the majority of the present standard 10-inch picture tubes use a magnetic field for each function.

During the past few years there has been an improvement in the appearance of the television picture as a result of the flattening of the face of the bulb. This trend seems to have reached a certain degree of stability using a bulb face with a relatively large radius of curvature rather than a real flat surface.

The television receiver designers of course, would like shorter cathode-ray tubes to aid them in building smaller, lower cost cabinet designs. Today, however, there is no apparent way of accomplishing this to a marked extent without introducing other features that are disadvantageous and tend to offset the gain of shortened length.

Transmitting Tubes

General

Unlike radio receiving tubes which, as a class, are highly standardized through the agency of the Radio Manufacturers Association, there is little such standardization in the field of radio transmitting tubes. In general, each make of transmitter requires the use of tubes specifically designed for it by one particular manufacturer. This probably makes obsolescence and development a more rapid process but, from the viewpoint of a user or purchaser of the equipment, it would appear to have some disadvantages. Type number designations, however, are assigned by a joint agency of the National Electrical Manufacturers Association, and the Radio Manufacturers Association. Formerly the system was a combination of numerals and letters, such as *9C24*, but the newer procedure on other than receiving and cathode-ray tubes is the assignment of a 4-number designation, such as *5518*, in which the numbers have no significance in regards to the size or characteristics of the tube. The custom of prefixing the type number by a manufacturer's letter identification continues.

One general trend in new designs is the increasing use of thoriated filaments[18] (except in the case of magnetrons) rela-

Figure 12 (left). A high-power transmitting tube for radio broadcasting

This air-cooled unit will dissipate 20 kw and weighs over 200 pounds

Figure 13. Moulded glass terminal header for a high-power tube

tive to pure tungsten and coated filaments. The so-called thoria-coated filaments, as distinct from thoriated filaments, are in limited use but it is doubtful whether this type of cathode will become commonplace.

Another general trend is toward forced air cooling for larger and larger sizes of tubes (Figure 12). Per kilowatt of output, an air-cooled tube is more costly than a water-cooled tube, but the manufacturers and users of radio transmitting equipment, particularly in the broadcasting field, greatly prefer air-cooled tubes.

Probably one of the most active, forward-looking laboratory developments not yet in production is the use of ceramics[13] for seals and terminal insulators to replace glass. This new material is of great interest because certain compositions have very low dielectric loss for the high frequencies at high temperatures. It also can operate at much higher temperatures than glass without softening or being subject to electrolysis. Another advantage is that it provides opportunities for new assembly procedures. As mentioned previously in this paper, this development is one of the two main contributions from enemy countries during World War II. In the case of ceramics, the idea that they could be used for this purpose is the chief contribution as the materials we are using in the United States and the methods of sealing them to other parts of the tube structure are being developed along very different lines than in Germany.

Some General Problems in This Field

When asked about ever-present problems, one engineer expressed it rather aptly by saying that one of the most troublesome ones was "getting more emission where you want it and less where you don't want it." In other words, more emission, particularly per unit of area, is constantly desired for cathodes, and at the same time grid emission must be minimized.

The designers of transmitting tubes also are being reminded constantly that designs are needed for ever-higher frequencies and once such a design has been produced, then the demand is for ever-larger and larger power ratings.

From the structural viewpoint, there is a constant urge toward closer interelectrode spacing and finer grids in triodes and tetrodes. This urge, of course, comes from the need for higher values of transconductance at low output impedance in order to get improved broadband operation particularly in frequency modulation and television.

One noticeable design feature in many of the newer tubes is the localized cooling of both filament and grid leads as well as certain areas of glass bulbs or seals subject to local heating. This is accomplished by both sharply directed air streams as well as water circulated through cooling ducts. The need for such cooling well might be eliminated by the use of ceramic materials.

Some Materials and Techniques

In large glass transmitting tubes, nearly all of the newer designs utilize moulded glass headers, the terminal pins all extending through this header (Figure 13). More recently, and particularly for the shorter wavelengths, the glass header is being replaced by one of metal and bushing type seals or their equivalent are being introduced (Figure 14). Thus in one way or another, there is a tendency toward eliminating glass, in so far as possible, in all tubes for very high power, particularly those for the shorter wavelengths.

In all except the smaller sizes of tubes, seals utilizing large wires through a pinched-off stem are being replaced by disks, cups or cylinders of alloy metals.

The metal zirconium is being used to an increasing extent as a coating on hot radiation-cooled electrode surfaces. It acts as a getter and also forms a surface having greater heat radiating properties than a shiny metal It is employed on a number of different base metals. For new designs having radiation-cooled anodes, graphite and pure tantalum do not seem to be employed as extensively as a few years ago.

For the ever-present grid emission problem, several methods are being worked on intensively but covering the surface with some form of platinum seems to be a favorite method.

Classification by Frequency

A convenient way to cover the subject of transmitting tubes is to group them into several classes based on broad frequency ranges:

1. Broadcast frequencies up to several megacycles.
2. Frequencies used in frequency modulation and television transmitters. This now extends up to 216 megacycles.
3. Frequencies from the previous value up to about 1,000 megacycles. This includes

Figure 14. A twin power tetrode for inputs up to 10 kw and for frequencies up to 300 megacycles

Figure 15. Forced air-cooled tetrode, incorporating seals and terminals

For outputs up to 1.5 kw at 110 megacycles. Designed for grounded-grid circuits

Figure 17. A small transmitting tube incorporating a ring-type grid terminal and suitable for use in a grounded-grid circuit up to 1,200 megacycles

(Over-all length about $3^1/_2$ inches)

the so-called citizens' band and the very large number of channels set aside for improved television utilizing either high definition of color or both.

4. Frequencies above 1,000 megacycles and commonly designated as microwaves.

Present Broadcast Range. There is not a great deal of activity in this field, particularly in the smaller sizes of tubes where requirements are pretty well taken care of by present designs and war stock surpluses are also a factor.

The feature of utilizing 2- or 3-phase filaments to minimize hum, which was common a few years ago, is not appearing in the newer designs. This is due partly to better hum compensation or balancing methods as well as the fact that the problem is less acute due to the lower currents utilized in thoriated filaments.

Frequency-Modulation and Television. This field is very active in requiring new designs (Figure 14) up to those large enough for a station rated at 50-kw output. One of the chief problems confronting the engineer in this field is that of obtaining more electron emission per unit area of the cathode. This factor has been improved over tenfold during the past few years but the urge to improve it still further continues. Many of the new types incorporate disk or ring-seal features for a grid terminal and are designed for use in grounded-grid circuits (Figures 15 and 16).

As has been noted, forced air cooling is favored by the users of broadcast transmitting tubes. In the past not too much attention has been given to the aerodynamics involved but this factor probably will be studied more thoroughly and marked improvements made in the newer designs.

The power gain per stage is an important factor but is tied up in a rather complicated way with several other factors.

Some engineers feel that magnetron developments may to a marked extent affect future activities in transmitting tubes for these frequencies. If such magnetrons can be designed with satisfactory output and efficiency and capable of modulation with low power, such a combination may well change the tube design picture. This is particularly true if the result is suitable for both frequency or amplitude modulation. Considerable research work in this field is going on.

Frequencies up to 1,000 Megacycles. There is not much activity in developing special tubes for the so-called "citizens' radio band" (460–470 megacycles). There seems to be a general feeling that this application might find satisfactory use on a small scale but in mass quantity use there are many difficulties. This has resulted in a "let's wait and see" attitude. There are tubes available for this application that will take care of present developments although that is hardly true for light portable transmitting equipment.

For the broad band of frequencies between 480 and 920 megacycles assigned to television developments, there is also considerable activity, but the situation is similar to that in the present television band. In other words, triodes and tetrodes utilizing certain features of disk-seal tubes are applicable in some cases (Figure 17) although the types of tubes suitable for the next higher range of frequencies are not being forgotten.

Ultrahigh-Frequency Tubes. At the present time, except for high-frequency heating, most of the applications, actual and proposed, are in the field of communication. The power ratings of such tubes are also relatively low although this is more a matter of inability to make high-power tubes except as oscillators.

There are a number of varieties of tube types which are useful in this frequency range. It is too early for a clear or final analysis indicating the position of each type and to where and what extent each will be used. The following comments seem to cover present engineering opinions:

Magnetrons[50]—These tubes are primarily oscillators not usable as amplifiers but are suitable particularly where high peak powers are required, such as radar. They are suitable also for generating continuous output high frequency and, as has been indicated, well might fit in the frequency modulation and television picture if satisfactory means of modulation can be developed. They appear also to have a very promising future in high-frequency heating at about 1,000 megacycles and above (Figure 18).

Velocity-Modulation Tubes[51]—These tubes are also designated as velocity-variation tubes and klystrons (Figure 19). They are useful as oscillators and amplifiers and lend themselves very readily to frequency modulation. They have proved to be exceedingly useful as signal generators and as power oscillators within the range of their ratings. The chief disadvantages are their relatively narrow bandwidth as amplifiers, low efficiency and relatively high level of inherent noise that limits their use as receiver amplifiers.

Traveling-Wave Tubes[4]—These tubes (Figure 10) have extraordinary capabilities as regards high gain in combination with an exceedingly broadband for amplification. They appear to be subject to somewhat the same limitations as to noise found in connection with klystron tubes. This tube is a relatively new development and accurate appraisal is not yet possible.

Disk-Seal Triodes and Tetrodes[52]—These now are limited in frequency to about 4,000 megacycles and have relatively low gains as amplifiers. Control of frequency and possibilities of satisfactory modulation are not

considered as good as in the klystron. Their outstanding advantage is their low signal-to-noise ratio making them suitable for low signal level amplification. Their capabilities as broad-band amplifiers are not as outstanding as the traveling-wave tube but are apparently sufficient for many applications.

Duotrons—These tubes are structurally similar to a triode but operate with a moderately noncritical transit angle and require a radio-frequency short circuit between cathode and grid. Since the grid and cathode have no radio-frequency potential difference, only one tuned circuit is required. They are the newest of the special types listed and very little information is yet available. They would appear to be particularly promising in fields that are now served by the klystron and disk-seal types.

Thyratrons and Ignitrons for Industrial Control

Thyratrons

Here the most pronounced trend is the increased use of an inert gas filling in place of mercury vapor. The object of this change is to make the operation of the tube and its characteristics independent of ambient temperature over a very wide range. The variation of operation with temperature often presents difficulty in the application of mercury-vapor tubes due to the great change in vapor pressure with change in temperature of the mercury. Indirectly the elimination of the mercury vapor helps to shorten the warming-up time. This independence of ambient temperature is also very helpful in fitting in with the modern trend toward totally enclosing industrial control equipment in steel cabinets. The inert gas used is pretty generally xenon. The real problem in this substitution of an inert gas has been to prevent the "clean-up" of the gas which resulted in short life. The attack on this problem has been along two lines, the first involving circuit arrangements[33] to lower the rate of change of inverse anode voltage on the tubes. The second improvement lies in the design and processing of the tubes themselves.[34]

Much progress has been made in both these directions. The circuit in which the tube is used is still a factor but less vital than it was a year or two ago. Tube designers are quite confident that in the not too distant future they will be able to build gas-filled tubes giving an entirely satisfactory life under almost all required circuit conditions within the rating of the tube.

As a part of this program of improved tube design, the deionization time[35] has been decreased. This also permits tubes of the new design to be used at frequencies higher than 60 cycles. This is a favorable condition toward possible general application on the 400-cycle power supplies used in some aircraft and for other special conditions.[36]

Thyratrons are now available in miniature dimensions for control and instrumentation applications where the average current requirement is in the milliampere range. Quick heating of the cathodes (one minute or less) is considered a very desirable characteristic by the users of thyratrons. This feature is increasing the use of filamentary cathodes rather than heater cathodes in many of the newer designs.

Thyratrons are made in both metal and glass envelopes. Industrial users of this class of tubes tend to favor the metal types on the basis of their being sturdier but cost is the real determining factor in the choice of envelopes. At the present time in considering new designs, an average current rating of about ten amperes is the dividing line. For a rating smaller than this, glass envelopes are indicated, and for higher ratings, steel envelopes.

A 25-ampere average current rating is at present about the largest size of thyratron commercially available. For tube current ratings above that value, ignitrons are favored. Thyratrons are being applied more frequently at higher voltages. An example is in the power supply for high-frequency heating equipments.[3] Quite a number of years ago, the shield-grid design of thyratron[38] was brought out as a distinct type. Now most new thyratron designs have incorporated in their structure what amounts to a shield electrode. Their classification as shield-grid thyratrons, however, depends upon whether the electrical connection to this shield is part of the cathode structure or whether it is brought out to a separate base terminal. In the latter case they are distinctly in the class of shield-grid tubes (Figure 20). In general, this feature of an independent connection to the shield is more common in the small tubes used entirely for control operations than in the larger tubes where power conversion or power output is usually the predominate use.

Air cooling of thyratrons rather than water cooling is practically universal.

Sealed Ignitrons for Control Applications

There has not been a great deal of change in design of these tubes for a number of years nor in general have any new types of larger or smaller ratings been added. The present available types seem to be meeting the requirements in a satisfactory manner. Use of steel en-

Figure 18. A 5-kw water-cooled magnetron designed for high-frequency heating at 915 megacycles

(Over-all length about 9 1/2 inches)

Figure 19. A klystron with frequency range of 2,000 to 4,000 megacycles

Figure 20. Shield-grid thyratron for industrial use

velopes is almost universal for ignitrons and all except the smallest available sizes are designed for water cooling.

Ignitrons for welding control are available and their application economically sound for use at much lower average current ratings per anode than in the case of ignitrons for power conversion. This is due to the fact that the peak current rating for the tube is the important factor in welding control rather than the average current. An ignitron with an average current rating of only about 12 amperes has a peak current rating as high as about 1,000 amperes for some duty cycles. Thus we may have the rather surprising combination of a 12-ampere average ignitron requiring a thyratron to fire it that has a peak current rating considerably higher than this figure.

The sealed type of ignitron has supplanted completely the pumped type in the welding control field.

A number of years ago, it was hoped that a pair of ignitrons connected "back to back" constituted an almost universal form of a-c switch or contactor or even a regulator having unusual characteristics that would find many other applications in addition to welding control. To date this hope has not materialized. The most promising new application is in connection with the operation of large d-c motors from an a-c supply line.[29]

Sealed Ignitrons for Power Conversion

One of the most interesting trends in tubes of this class is the marked tendency toward the use of larger sizes. In other words, the line of demarkation between the sealed units and the pumped units is rising to larger and larger ampere ratings. Last year sealed tubes rated at 400 amperes per anode were introduced[30] and now are finding ready acceptance. This represents about a doubling of the amperes per anode over the previous largest size. Another doubling of this factor and a great many of the applications now served by pumped tubes can be handled by sealed-off types.

The single anode type of tube (Figure 21) that always has characterized the ignitron was adopted for the pumped type of rectifier a number of years ago and now almost has superseded, at least in the United States, the multianode unit. In England and in Europe, however, multi-anode tubes are still in the majority and what to American engineers appears to be huge glass bulbs are in common use over there. There has been a decided trend also in the past few years to operate ignitrons at higher voltages[31] than the 250 and 500-volt d-c ratings that formerly comprised the majority of applications. They are now being built and used in connection with power conversion equipments up to 20 kv[32] (Figure 2). They also are finding their place in the power supplies for high-power radio transmitters.[33,34] The sealed ignitron mercury pool tube has so far failed to find application in the lower current ratings. This is not directly due to any design feature in the tube itself but rather to the fact that the cost of ignitron firing circuits is high and is almost a constant figure regardless of the output rating of the ignitron that it controls. Therefore, as the ratings of a rectifier become smaller and smaller, the expense of the firing circuits does not decrease, and finally the cost of this auxiliary is so high in comparison with the rest of the rectifier that the over-all result is not economically sound. At the present time this lower limit for an economical design of sealed pool tube rectifiers is at about 100 amperes per anode. This situation represents one of the problems confronting engineers

Figure 21. Cut-away view of a water-cooled typical sealed steel-envelope ignitron as used for power conversion

active in the development of tubes of this general type for wider applications.

Considerable thought and effort, therefore, are being given to the development of ignitors that require much less current than the present ones that take a maximum of about 25 amperes.[35] This is far from an easy problem in view of the outstanding performance of present-day ignitors as regards life and reliability. Life of a modern ignitron is measured in years rather than in a few thousand hours and it naturally requires considerable time to develop new devices with the assurance that these long life records will be maintained.

Most large steel envelope sealed ignitrons contain two separate ignitors. In view of the long average life obtained in modern tubes the question has been raised as to whether two ignitors are really necessary or advantageous. The concensus of opinion seems to be that two ignitors will be continued as a design feature. They represent low-cost accident assurance against ignitor breakage or burn-out resulting from trouble in the firing circuit. Designers of these tubes point out, however, that when a tube finally fails after many years of satisfactory service it is usually from some other cause than ignitor failure and, therefore, it is seldom that the spare ignitor can be used to rejuvenate completely the tube and start it off on a second career of long life.

THE scheduled completion on October 26, 1948, of the change in frequency from 50 to 60 cycles of the Southern California Edison Company system and its customers' frequency-sensitive utilization equipment will bring to a close the largest program of its kind ever undertaken in the history of the electrical industry.

The frequency of 50 cycles was established in southern California in the year 1893 when a group of pioneer utility men placed into operation the first 3-phase hydroelectric generating units for commercial use in the United States, and it is believed, in the world. These units, consisting of two 250-kw 2,200-volt generators, were installed for local use near Redlands, Cal., a distance of approximately 75 miles from Los Angeles. This early installation was the beginning of the development of a number of small and isolated systems throughout southern California, all of which developed at 50 cycles, and later merged with, or were acquired by, the Southern California Edison Company.

The decision of this pioneer group to use a frequency of 50 cycles was based upon the economics of generating and transmitting electric energy for lighting and power purposes where the load centers were remote from the source of generation, and long distances of transmission were involved.

At the time these early installations were made in southern California, there had been no standard established for the frequency of a-c generation, as many of the utilities throughout the country were experimenting with frequencies ranging from 25 to 133 cycles, depending upon the class of service rendered. It was not until after the turn of the 20th century that frequencies tended to standardize at 60 cycles in the United States, while in Europe and most of the rest of the world, frequencies were standardized at 50 cycles.

During these early developments in southern California by the privately-owned utilities, a number of municipally-owned systems were established also in and around Los Angeles, principally in the cities of Burbank, Glendale, Los Angeles, and Pasadena, all of which developed at 50 cycles. As a result, the major portion of the area in southern California, with the exception of the San Diego Gas and Electric Company, the territory served by the California Electric Power Company, and a small portion of the city of Los Angeles served by the Los Angeles Gas and Electric Corporation, developed at 50 cycles.

With the advent of Hoover Dam power and the acquisition by the Department of Water and Power of the City of Los Angeles of the properties of the Los Angeles Gas and Electric Corporation in 1936, the Department of Water and Power changed the frequency of its system to 60 cycles. This also necessitated the cities of Burbank, Glendale, and Pasadena to likewise change their systems to 60 cycles as the Department of Water and Power is the generating and transmitting agent for Hoover Dam power to these cities.

Since the conversion of these cities to 60 cycles did not materially affect the company's operations, it was not until the war was well advanced that the company gave consideration to the change of its system to the higher frequency. This consideration was brought about because of the large amount of frequency-sensitive items of equipment installed during the war for which the company's customers were required to pay premium prices for 50-cycle equipment, and it appeared this price situation would continue post-war.

On June 8, 1945, the executive committee of the board of directors authorized filing an application with the Public Utilities Commission of the state of California for authority to change the frequency of its system from 50 to 60 cycles. Following a public hearing, the commission, on July 27, 1945, issued its order directing the company to proceed with the establishment of a uniform system-wide a-c frequency of 60 cycles and to cease rendering 50-cycle service at such time as it was in a position to render 60-cycle service in lieu thereof. The commission's order further provided that the company assume, in addition to the conversion costs of its own equipment, the reasonable direct costs of adapting customers' appliances and equipment for proper operation at a frequency of 60 cycles.

The cost for the conversion of the company's system and its customers' utilization equipment is now currently estimated at $35,000,000, of which approximately $33,000,000 is chargeable to operations and the balance to plant.

Scope and Size of Conversion Program

From the early beginning of the company's system in 1893, the company ex-

Paper 48-127, recommended by the AIEE system engineering and transmission and distribution committees and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 27, 1948; made available for printing March 11, 1948.

H. W. TICE is vice president in charge of operation and A. A. KRONEBERG is senior electrical engineer, both of the Southern California Edison Company, Los Angeles, Cal. W. N. JOHNSON is manager; J. D. ENEFER is assistant manager; E. E. TUGBY, planning engineer and C. L. SIDWAY, principal engineer, all with the frequency change department of the Southern California Edison Company.

Figure 1. Transmission system of Southern California Edison Company

panded in less than 55 years to become the fifth largest privately-owned electric utility in the United States in kilowatt-hours generated. The service area of the company covers approximately 18,000 square miles with a system power demand in excess of 1,000,000 kilowatts with an annual generation of approximately 6,000,000,000 kilowatt-hours. The company's system serves directly some 75 incorporated cities and 150 unincorporated communities and outlying rural territories. It also supplies energy for redistribution to four municipalities at 50 cycles and to three privately-owned utilities on a wholesale basis at 60 cycles. The territory served includes large areas devoted to farming and fruit growing, much of which is made possible by irrigation. Among the more important industries served are the production and refining of oil, production of motion pictures, fruit packing, the manufacture of cement, rubber tires, chemicals, airplanes, oil well equipment, automobiles, and the production and fabrication of iron and steel. In addition, the company serves two electric railways, the Pacific Electric Railway Company operating a system of interurban electric lines in the vicinity of Los Angeles, and the Los Angeles Transit Lines operating electric streetcar lines and trolley busses serving the city of Los Angeles.

Figure 1 shows the territory served by the company and its major transmission system and generating plants.

The number of customers served by the company as of December 31, 1947, totalled 765,000, of which approximately 700,000 were served from the 50-cycle system now under conversion, and the balance at 60 cycles. The 60-cycle service area is located in the San Joaquin Valley where the company acquired the 60-cycle properties of the Mount Whitney Power and Electric Company in 1920 and has since continued serving this area at this frequency.

The foregoing briefly outlines the development of the Southern California Edison Company into a single integrated system serving a highly developed agricultural and industrial area, and is set forth so that the reader may have some idea as to how and why the company's system developed at 50 cycles, and the magnitude of the work involved in converting its system to the now generally accepted United States standard frequency of 60 cycles.

Physical conversion of the company's system commenced September 6, 1946, and it is estimated that, as of June 1, 1948, the company will have completed the conversion of 525,000 customers, representing 75 per cent of the total, and 1,600,000 horsepower of connected load, representing 78 per cent of the total project.

The conversion is being made concurrently with an unprecedented load growth in the territory served by the company which requires the planning and construction of new generating and new step-down substations. The 1946–1947 season was one of subnormal precipitation on watersheds of the company's hydroelectric developments and the 1947–1948 season to date is even more deficient in this respect. Operation at two frequencies and outages of steam-electric units for rebuilding tremendously complicate the problem of dry-year operation. Deferred maintenance and repair work that accumulated during war-time operations add their share to the complications of the system conversion. In spite of these complications, however, it is expected that the change of the company's frequency from 50 to 60 cycles will be completed on schedule in October, 1948.

System Engineering and Operation*

Preliminary engineering of the frequency conversion included investigations of existing equipment and its ability to operate at the higher frequency. The following are fundamental relationships involved in studies of frequency conversion:

1. The frequency of a generator is proportional to the number of poles and to the speed of the rotor.
2. The voltage is proportional to the flux and to the frequency.
3. The reactance ohms are proportional to the frequency.
4. The maximum power input to an inductive circuit with a variable resistance load is proportional to the square of the applied voltage and inversely proportional to the frequency.
5. The centrifugal stresses in rotating parts are proportional to the square of the speed, that is, to the square of the frequency.

Prime Movers

The investigation was begun with a study of prime movers and their performance at variable speed. Nearly all prime movers of generating units on the system of the Southern California Edison Company are turbines. Typical characteristics of torque versus speed and power output versus speed of a turbine are illustrated in Figure 2. Normal speed and 120 per cent speed are indicated on the curves. It may be noted that a higher than normal speed the power output decreases.

The input to an impulse turbine or water wheel is independent of its speed, hence the reduction of output at higher than normal speed is a loss of efficiency. This loss of efficiency results from buckets leaving the line of action of the jet before every bit of water completes its work upon the buckets, and some of the water is therefore not utilized. Where this loss of efficiency is of sufficient magnitude to justify the cost of rebuilding, the wheel diameter is reduced and new buckets of altered design are installed. The company is rebuilding wheels at Big Creek 2-A powerhouse where they are driving two 45,000-kw generators and at Kern River number 1 powerhouse, where four 5,000-kw generators are in service. Some 14 water wheels out of a total of 54 are scheduled for rebuilding.

In the radial-flow type of turbine the water is subjected to centrifugal forces. The centrifugal force opposes the flow of water in the case of the inward-flow turbine so that, as the speed increases under constant head, the discharge tends to decrease. Thus, with a reduction of both input and output, the efficiency of the turbine may change little or not at all. In turbines operating under conditions of low head and large quantity of water, the increase of speed may introduce or intensify cavitation. The company is equipping the three 50-cycle units at Hoover Dam with new runners of smaller diameter and with fillers to fit them into the existing stationary parts. The other 12 turbines on the company's system require no major changes for operation at 60 cycles.

Steam turbines are subject to additional

Figure 2. Typical output characteristics of a turbine

* H. W. Tice and A. A. Kroneberg.

complications when operated at the higher speed. The elastic limit of materials is reduced at the very high temperatures to which turbine blades are subjected. The increased centrifugal forces at the higher speed may exceed the elastic limit and may cause a permanent elongation of the blades (creep). A steam turbine rotor is a complex structure of disks and blades all having their natural periods of vibration. The rotor is "de-tuned" for the normal design speed, that is the disks and blades are designed for natural periods of vibration other than normal speed. The critical speed of the precision-built, highly efficient turbines is too near the 120 per cent normal speed to permit safe operation at the latter speed. Of the eleven steam-electric units operating on the company's system, three are old and relatively inefficient vertical units that cannot be opeated at the higher speed. Units *4* to *8R*, inclusive (5), are 60-cycle units originally adapted for 50-cycle operation or installed to replace 50-cycle units removed during the war. The remaining three units are the largest and latest of the 50-cycle units installed on the system. Their operating capacities are 60,000 kw; 100,000 kw; and 100,000 kw. Parts for rebuilding turbines have been purchased for these three units.

There are five diesel-electric units in operation in a leased plant connected to the company lines. These units are rated approximately 5,000 kw each. The engines were required to be operated as near to their design speed as possible. The generators were rebuilt from 50-cycle 36-pole machines to 60-cycle 42-pole machines. The operating speeds are 166.7 and 171.5 rpm, respectively. This resulted in an increase of only 3 per cent in the speed of the diesel engines.

Synchronous Machines

Currents in windings of synchronous machines (generators, condensers, and motors) have limiting values established by heat produced in the resistance of the windings. These limiting values are held unchanged for operation of the machines at the higher speed. However, maintaining field currents at the same values at either speed means operation at constant flux and the varying of voltage in proportion to the speed. This increase in voltage, if it can be sustained on the existing insulation, is highly desirable from the standpoint of over-all system performance. Ohmic reactances are expressed as percentages or per unit values for use in system-wide studies on a given kilovolt-

Figure 3. Schematic diagram of the 220-kv backbone of the system

ampere base. Those values represent the ratio of the IX drop to the rated circuit voltage E. Since X varies with the frequency and I for a given base varies inversely as the voltage E, it is apparent that the per unit value of reactance varies directly as the frequency and inversely as the square of the voltage. Low reactance is the prime factor in the steady-state stability of a power system, and is second only to high speed of fault clearing in the transient stability of the system. The maximum increase of voltage on synchronous machines permitted by insulation levels and by available transformer ratio taps is being made at the time of change to 60-cycle operation.

Another important factor in the transient stability of a power system is the inertia constant of a synchronous machine derived from its WR^2 and speed. It may be defined as the time required for the machine to decelerate from full speed to a complete stop with rated torque acting through the entire period of time. With full speed increased to 6/5 of the original speed, WR^2 unchanged, and rated torque reduced to 5/6 of the original torque, the time to come to a stop or the inertia constant is increased to 144 per cent of the 50-cycle value. Further analysis of the inertia constant and its effect on machine performance reveals that it takes 20 per cent longer for a machine to reach a displacement in phase angle of the same number of electrical degrees at 60 cycles than it does at 50 cycles. The effect of increased frequency upon inertia constants of synchronous machines is, therefore, inherently stabilizing and beneficial to the power systems.

The shafts and rotors of synchronous machines are subjected to mechanical stresses and torques. The torques are decreased with increased speed of operation. Centrifugal forces, however, increase as the square of the speed. The rotor structures of rotating machines must therefore be checked for factors of safety used in their design and strengthened or replaced if factors of safety are not deemed to be adequate. Particular attention is paid to stresses in dovetails and in pole tips of salient-pole synchronous machines. Water-wheel generators are designed to withstand runaway speed which is nearly double the normal speed. Operation of water-wheel generators at 120 per cent rated speed is therefore feasible and safe. Steam turbogenerators are not expected to be subjected to speeds in excess of 110 per cent normal because of prime mover design limitations. In view of the importance and the size of the three steam-electric units for which turbine parts have been purchased, they are also being equipped with new generator rotors.

Synchronous condensers are required by AIEE standards to be able to withstand a 25 per cent overspeed. A study of some 19 50-cycle machines on the company's system disclosed factors of safety ranging from 2.5 to 6.0. These factors of safety are reduced to 70 per cent of their original value when the machines are operated at the 60-cycle speeds. Proper weight was given in the study to the age and condition of machines, and to the possibility of obtaining increased capacity economically through complete rebuilding.

The company's program includes the complete rebuild of two 30,000-kva condensers to increased capacity of 45,000 kva each, the purchase of new rotors for five synchronous condensers, and the purchase of sets of new poles for rotors of four synchronous condensers and two machines comprising a frequency changer. The 60-cycle machine of this frequency changer required new poles because it was not designed for starting and a starting winding was necessary for operation as a condenser upon completion of frequency conversion.

The bearing losses in synchronous machines increase as approximately the 3/2 power of speed. In ring oiled bearings, more oil is carried by the rings at higher speed to cool the bearings. Experience of other utilities and that of the company indicates that performance of bearings at the higher speed is unpredictable, but in general, satisfactory and occasionally even improved over original performance. Direct connected and motor driven exciters operating with voltage regulators are expected to give satisfactory performance at 60-cycle speeds. Necessary reinforcing of commutators or notching of pole pieces are details left for determination by tests and detailed engineering.

Transformers and Lines

It is intended to operate power and distribution transformers on the company's system at the same voltage at 60 cycles as they were operated at 50 cycles. The voltages are determined by insulation levels of transformers, busses, transmission and distribution lines, and other equipment. Since voltage is proportional to frequency and to flux, an increase in frequency will result in a reduction of flux and flux density. A reduction in flux in turn means reduced magnetizing current and reduced hysteresis loss. No detectable changes are expected in copper losses and eddy current losses as a result of increased frequency. The reduction in core loss permits an increase of voltage to 107 per cent and a corresponding increase in rated kilovolt-amperes. Similarly, if voltage remains unchanged, the load current may be increased to 103 per cent with a corresponding increase in rated kilovolt-amperes. Tests on representative distribution transformers indicate a reduction of core loss at constant voltage of a little less than one watt per kilovolt-ampere of transformer capacity. Transformer reactance will, of course, be increased to 6/5 of the 50-cycle value and there will be a corresponding increase in regulation.

Characteristics of transmission and distribution lines will be adversely affected by the change of frequency. Reactance and susceptance per mile of line increase with the frequency. Both values enter in transmission line calculations in such a manner that, disregarding effects of conductor resistance, it may be said that a 60-cycle transmission line has approximately the same characteristics as a 50-cycle line 20 per cent longer. Stated differently, it means that the change of frequency is equivalent to increasing the distance of transmission. On short lines of low and medium voltage, it is merely an increase in impedance and regulation. On long high voltage lines, it also means increased requirements of kilovolt-ampere capacity for charging the line. The per cent increase of charging kilovolt-ampere is more than the per cent increase of frequency, but less than the per cent increase of the square of the frequency. That is, charging kilovolt-ampere will increase to a value between 120 and 144 per cent of the 50-cycle kilovolt-ampere. The per cent increase of voltage rise along an unloaded line will also be considerable. As an illustration, the voltage rise along a Hoover-Chino 220-kv line is 10 per cent at 50 cycles, and is 15 per cent at 60 cycles. The resistance of aluminum cable steel reinforced conductors in use on the company's high voltage transmission lines will be increased very slightly as a result of skin effect. This increase is approximately 7/10 of one per cent.

System Stability

The term "power system" is applied to the combined interconnection of generators, transformers, transmission lines, synchronous condensers, and so forth. The power system combines characteristics of its component parts into characteristics of its own. The more important of these are the steady state and the transient stabilities. Studies were made to determine the extent to which increased voltage of synchronous machines and the corresponding decrease in their per unit reactances were able to offset the increase in transformer and transmission line reactance. The effects of the frequency conversion upon the steady state stability of the company's system are illustrated by the following two summations of reactances of generators, transformers, lines, and remaining system:

50 cycle: $0.60 + 0.11 + 0.47 + 0.26 = 1.44$
60 cycle: $0.53 + 0.13 + 0.56 + 0.26 = 1.48$

The ratio of the two summations, 0.97, indicates an approximate loss of 3 per cent in steady-state stability resulting from the change of frequency. Studies of transient stability indicate that although transient reactances of the branches of the system show a net increase of approximately 10 per cent, the permissible time of clearing a fault has increased 20 per cent owing to increased inertia constants, the net result being practically the same transient stability within the practical range of fault clearing of 0.2 to 0.5 second.

Figure 4. Temporary connection for switching circuits from 50 to 60 cycles

(A) From operating to temporary bus
(B) From operating to transfer bus

The preliminary engineering studies outlined before determined the major items of change in system equipment and were followed by detailed engineering of the changes. This included preparation of specifications, ordering of equipment and parts, investigation and engineering of changes in auxiliaries and accessories, and scheduling the work of conversion.

System Operation

With equipment to be rebuilt designated by the engineering studies, and the outage times for rebuilding estimated from best available information, it was necessary next to develop a master plan for operation of the system during the conversion of frequency. The conversion, requiring a minimum of two years to carry out, had to be coordinated with system expansion called for by the rapidly growing load. Contractual obligations and limitations of interconnections with adjacent utilities introduced additional complications in the planning of operations. The master plan had to be flexible enough to allow for possible delays in obtaining materials without disruption of conversion schedules.

The company's system may be described as follows: The backbone of the system is a 220-kv three-circuit transmission line shaped like a right angle *L*. The bulk of generation is divided into three almost equal groups. One, Big Creek, a group of hydroelectric generators, is located at the top of the *L* in Fresno county; the second, Hoover, a United States Bureau of Reclamation project on the Colorado River, is connected to the other end of the *L*; and the third, Long Beach, where a group of steam-electric generators are clustered at the apex of the right angle. The distance from Long Beach to either of the hydroelectric groups is approximately 280 miles. Fourteen substations break up the transmission line into 28 sections not counting the line of the Metropolitan Water District of Southern California, which is used jointly by the district and the company. Two of the substations (Pisgah and Gould) are switching stations only; five substations (Piedra, Rector, Vestal, Magunden, and Highgrove) are step-down substations supplying 60-cycle power to the San Joaquin Valley load of the company and to interconnections with other utilities; and seven substations, (Saugus, Eagle Rock, Laguna Bell,

Figure 5. Map of geographic conversion area: of Southern California Edison Company

Lighthipe, La Fresa, Chino, and Barre) are 220/66-kv step-down substations supplying the main part of the company's load.

This load, of approximately 90 per cent of the total, is the 50-cycle load being converted to the standard frequency of 60 cycles. Each of these seven major substations is a source of power for one or two sub-transmission systems of 66-kv transmission lines and step-down substations. There is a total of some 90 such step-down substations involved in the change of frequency, ranging from a simple line tap and a transformer to a switching and step-down substation with a ten-position double bus arrangement. Transformers at these substations step the voltage down to 16.5 kv or 11 kv for high voltage distribution, and to 4 kv or 2.4 kv for primary distribution and for customer distribution systems. There are some 110 substations stepping voltage down from high voltage distribution to 4-kv primary distribution, some 900 substations supplying individual customers and 90,000 line transformers for supplying 700,000 odd customers. Approximately 1,100 distribution and primary circuits in the 50-cycle areas are subject to independent switching at a bus and represent the minimum unit for simultaneous switching from 50- to 60-cycle service.

Main System

In planning the conversion of generating plants to 60 cycles, it was desired to convert each of the three major sources of generation in proportion to the demand of the converted load. This, however, was not entirely feasible because of the large size of some generating units and capacities of transmission lines which made rather large steps of conversion, and because of the long outages for rebuilding which required a staggering of conversion schedules.

Some flexibility in the planning of generation during conversion was obtained from the ability of some units to operate satisfactorily at either frequency with a minimum of adjustments. All units at the Big Creek plants can be changed from operation at one frequency to the other in a short time. The 90,000-kw unit *A-5* at Hoover Dam can be and has been operated at either frequency. The 82,000-kw steam unit *8-R* at Long Beach is equipped with two governors and can be switched from one frequency to the other without bringing it to a stop. Units *4*, *5*, and *6* at Long Beach, totalling 23,000 kw, can be operated at either speed following a shut-down for changes in governor weights.

Additional flexibility in the planning of production was provided by the existence of two 50,000-kw frequency changers at Chino and Highgrove substations. These frequency changers were made up of pairs of synchronous condensers coupled together for this service. Following completion of the program of conversion, they will be uncoupled and placed in service as condensers.

It was originally intended to divide the 220-kv backbone into two systems operating side by side, one at 50 cycles and the other at 60 cycles, the two being interconnected through the two frequency changers.

The company operates high-voltage interconnections with several adjacent 60-cycle utilities. In the north near Big Creek, the interconnection is with the 2,000,000 kilowatt system of the Pacific Gas and Electric Company. In the south, the interconnections are with the Metropolitan Water District and

Arizona utilities, the Department of Water and Power of the City of Los Angeles, the San Diego Gas and Electric Company, and the California Electric Power Company, all adding up to more than a million kilowatts. Delay in obtaining and installing equipment for tie line control made it necessary to divide the backbone into three, rather than two, separate systems. One of these is the remaining 50-cycle system, the second a 60-cycle system identified with the Pacific Gas and Electric Company, and the third, a 60-cycle system identified with the Metropolitan Water District line.

The arrangement of the sub-transmission systems dictated the division of the territory served at 50 cycles into nine conversion areas. Areas numbers 1 and 9 were originally supplied from Chino substation. Area number 1 has been transferred to the newly constructed Highgrove substation at 60 cycles. Areas numbers 5 and 6 are supplied by two transformer banks and two sections of bus at Saugus substation and can be completely separated or paralleled on the bus at Saugus. Other areas are identified with major substations feeding them as follows: number 2—Barre; number 3—Lighthipe; number 4—La Fresa; number 7—Eagle Rock; number 8—Laguna Bell. The sequence of conversion was determined by the needs of the conversion of customer equipment within limitations of the ability to operate the system in such a sequence.

Figure 3 shows a schematic diagram of the 220-kv backbone of the system. The west line from Big Creek to Magunden and the Metropolitan Water District line from Hoover through Highgrove to Chino were operating at 60 cycles prior to the beginning of conversion. The west Big Creek line was extended to Saugus for the conversion of Areas number 5 and 6, then to Laguna Bell for conversion of Area number 8. Area number 1 was, at the same time, converted to 60 cycles and transferred to Highgrove substation. The conversion of area number 2 and of a 100,000-kw unit at Long Beach permitted the linking of all generating sources with a 60-cycle line by switching sections to make one Laguna Bell-Lighthipe-Long Beach line and one Hoover-Pisgah-Chino-Barre-Lighthipe line. After this, the 60-cycle system is gradually increased by transfer of line sections from the 50-cycle system. Tables I and II illustrate load checks made from time to time in order to keep control of loading of transmission lines and of transformer banks. The load checks shown in the tables were made at the half-way mark, that is, at the time when approximately half of the company's load was supplied at each frequency.

Subtransmission System

It is impossible to review in detail all the line arrangements and switching procedures planned and executed for the conversion of the subtransmission systems to 60 cycles, but some of the methods used in the planning of switching facilities and some exceptional installations deserve description. One of the principles of planning was to progress with conversion along the outside of loops formed by 66-kv transmission lines. Nearly all major substations and eight of the step-down substations are equipped with double 66-kv busses with each position connected to each bus through an oil circuit breaker. It is a simple matter of assigning one bus to 60-cycle service and the other to 50-cycle service for the period of operation at two frequencies. Twenty of the 90 step-down substations are simply transformer banks tapped from a line. These substations are usually of low capacity and, with the line, are switched over to 60-cycle service in one operation. Twenty-four substations have single bus or ring bus arrangement of switching facilities. These substations have no more than two line terminals and two banks of transformers to handle, and separation of lines and transformers can be made without temporary connections. An operating bus and a transfer bus arrangement is the prevailing arrangement at the substations of the company, being used at 38 substations for 66-kv bussing and is the standard arrangement at the lower voltages. When the number of positions on such a bus exceed five, it is usually necessary to install temporary connections for operation at two frequencies. The preferred practice is to string a temporary "cutover" bus parallel to the operating bus and to connect to this bus through disconnecting switches all circuit breakers except those scheduled for the last day of conversion.

It is not always possible to make installations of temporary busses at a substation, owing to lack of space and obstructions of various kinds. In such cases, a study is made and some other means devised for accomplishing the necessary switching. A cut in the operating bus at some ten locations permitted the operation of the stations at two frequencies. The transfer bus was used as a "cutover" bus at a number of locations where the time of conversion was of short duration. The diagrams of Figure 4 illustrate temporary connections of a circuit to the temporary "cutover" bus and temporary connections to the transfer bus when the latter is used for conversion.

Among the problems of line and bus switching, two are believed to deserve

attention. One is the installation of a third 66-kv bus at La Fresa, and the other is the method of conversion of area number 2. La Fresa substation is located in a zone subject to insulator contamination from salt-bearing mist from the Pacific Ocean and fumes from oil refineries and synthetic rubber plants. It has been the practice at this substation to clean insulators supporting the 66-kv busses every four months. This requires alternate outages of the two busses, which is feasible when operating at a single frequency. The substation was scheduled for operation at two frequencies during twelve consecutive months and, it being a source station, no bus outages could have been arranged during the year. For this reason, a temporary 66-kv bus was constructed paralleling the length of the north bus and connections were made to it from 14 lines in a manner similar to connections made to cutover busses at other substations.

At Barre substation, one 75,000-kva transformer bank supplies area number 2, which comprises the entire territory of Orange County. The 60-cycle source of power for area number 2 was established at Chino substation, some 25 miles distant and two 66-kv lines were routed into the area by means of temporary connections at crossover points and by-pass connections at some substations. Approximately half the load in the area was converted to 60 cycles by progressive switching to these lines. At this point, the remaining 50-cycle load was transferred to Lighthipe substation through similar line changes, thus completely relieving Barre substation. The substation was then switched to 60 cycles with the 220-kv line sections and busses. It was again loaded with its 60-cycle load switched back to it from the Chino lines, and the conversion was completed by progressive switching of converted load from Lighthipe to Barre substation.

The method of conversion of Area number 2 illustrates the method commonly used in converting substations with one bank in service when sufficient spare capacity is available at adjacent substations, and when sufficient circuit capacity is available between substations to carry the load. When such capacity is not available, it is necessary to install temporary transformer banks to provide the needed capacity and frequency. Temporary transformer bank installations were required at 16 of the 66-kv step-down substations and at many of the 16.5/4 and 11/4 kv substations. The company purchased two 3,000-kva mobile substations with taps suitable for operation at 16.5/4 or 11/4 kv substations. These mobile units are currently in service as temporary 60-cycle banks at substations under conversion. They are scheduled to remain at various locations from two to five weeks and to be in transit an average of one week.

System operations for frequency conversion are conducted under the direction of a three-man committee. This committee plans the operations in accordance with the requirements of the frequency change department and co-ordinates them with regular system operations. It designs the required temporary connections and programs the switching procedures. The temporary connections are installed by the maintenance and construction crews of the operating department and all the switching is performed under the direction of the system dispatcher.

Conversion of Customers' Equipment*

Organization of Frequency Change Department

Immediately following the order of the Public Utilities Commission to proceed with the conversion of the company's system to the higher frequency, a separate frequency change department was organized to handle all phases of the project pertaining to the conversion of customers' equipment.

This department was organized on the basis of contracting the preponderance of the conversion work to local concerns so as to avoid taking onto the company's payroll a large number of employees whose services would, of necessity, be terminated at the conclusion of the project. Accordingly, five major contracts were awarded. The Bechtel Corporation and the Stone and Webster Engineering Corporation were employed to perform the survey, engineering and conversion of commercial and industrial customers' equipment; the California Electric and Maintenance Company, the survey and adaptation of domestic customers' appliances and equipment; the Fluorescent Maintenance Company, the adaptation of fluorescent and mercury vapor lighting units; and the California Electric Service Stations, the adaptation of electric clocks and timing devices.

The principal functions of the frequency change department are to co-ordinate the activities of the contractors' organizations, and to establish the rules, regulations, and policies covering the manner and extent of changes required to be made in the equipment of its customers. In addition to these functions, the department also handles all customer relation problems, newspaper releases, processing of records, mailing of pamphlets and cutover notices, operation of clock depots for the exchange or cycle-change of clocks, scheduling of the cutover of feeders, review of purchases and subcontracts made by the contractors, review of the engineering determinations and conversion methods employed by the contractors, development of basic engineering changes required to be made in specialized items of equipment, and accounts for the costs of the project.

The only physical work of conversion performed by employees of the department is the changing out, relagging and testing of watthour meters installed on the customer's premises, and the testing and adaptation of deep-well turbine pumps.

The number of employees engaged in frequency change work by the contractors and the frequency change department at the peak of operations approximated 1,777 of which 651 were employed by the department.

Basic Rules, Regulations, and Procedures

In ordering the company to proceed with the conversion of its system to a uniform system-wide frequency of 60 cycles, the Public Utilities Commission required the company to assume, within reason, the direct costs of converting its customers' appliances and equipment for operation at the new frequency, but declared that the adaptation of customers' equipment was a joint undertaking to be assumed by both the company and its customers, and that the company in providing such assistance to its customers must be governed by uniform nondiscriminatory procedures. The commission further required the company to prepare a Frequency Change Manual setting forth the policies, procedures and basic engineering data to be followed in the adaptation of customers' equipment, and to place this manual on file for public inspection in each of the company's district offices.

The following are excerpts from the "Rules and Regulations" as approved by the Public Utilities Commission:

"The company, except as otherwise herein provided, has the responsibility for adapting customers' utilization equipment to render it capable of performing essentially the

* W. N. Johnson, J. D. Enefer, E. E. Tugby, and C. L. Sidway.

same service when supplied from a 60-cycle system as that previously obtained when supplied from a 50-cycle system.

"The company, or its contractors, will make the necessary changes required to adapt the customers' utilization equipment in accordance with the company's engineering determinations. The customer will, without charge, make his utilitization equipment available for adaptation and provide necessary assistance to avoid delays during the progress of the work.

"The cost of additions, betterments, repairs, or maintenance of customers' utilization equipment is not a part of the reasonable cost of adaptation. Any such work shall be performed at the expense of the customer.

"A customer may assume the responsibility of adapting his utilization equipment and in such case the company will make a conversion allowance in lieu of adaptation.

"In exceptional cases or unusual circumstances where utilization equipment cannot be adapted for 60-cycle operation at a reasonable cost because of its condition, age, inadequate, obsolete or nonstandard design, the company will make a conversion allowance in lieu of adaptation.

"Rotating equipment will require adaptation only if it is speed critical and in such mechanical changes will generally be made in the drive or driven equipment. Where mechanical changes are, in the opinion of the company, not practicable, electrical changes will be performed.

"The company's responsibility for the adaptation of the customers' utilization equipment shall cease and terminate 60 days after the date of cutover, except as otherwise provided in this rule and regulation.

"In the event any customer's equipment is damaged, as a result of the conversion to a frequency of 60 cycles, the company and its contractors will be liable only if such damage is due to the negligence of the company, or its contractors. Such liability shall be limited to the repair of the damaged equipment.

"The company and its contractors shall not be liable for loss or damage, including but without limitation, loss of use, production, or profits resulting from the adaptation of the customers' utilization equipment, or from the conversion of the company's system to a frequency of 60 cycles, except as provided in the paragraph immediately preceding."

Plan of Conversion

The plan of conversion as originally submitted to the Public Utilities Commission under the company's application contemplated that it would require approximately one year for organizing, scheduling, and pre-engineering the work, and $3^1/_2$ years for the physical conversion, with the project scheduled for completion by the middle of 1950.

Subsequent studies developed the fact that, because of the unprecedented load growth and increase in population in the territory served by the company, important savings could be effected by shortening the physical conversion to two years. Accordingly, the program was revised to proceed with the conversion in two areas simultaneously, with completion scheduled for October 26, 1948. For conversion purposes, the company's system was divided into nine geographical areas, with each served from a major 220-kv substation. Figure 5 shows the location of these areas and the reference number assigned to each. Under this plan, the Stone and Webster Engineering Corporation was assigned the survey, engineering, and conversion of commercial and industrial power customers in Areas 1 to 4 inclusive, together with two electric railway systems; and the Bechtel Corporation, Areas 5 to 9 inclusive; with each contractor assigned approximately 1,000,000 horsepower of connected load.

Figure 6. Chart of work loads by months

A distribution feeder was established as the basic unit for conversion. Studies were made by classification and number of customers, the horsepower of the connected load of each, and the number of deep-well turbine pumps connected to each feeder, and from these data, area cutover schedules were established so as to provide an optimum work load for the several contractors. Figure 6 shows the project work load chart in total number of customers and connected power load in horsepower to be cut over each month. It is to be noted that during May and June 1948, customer conversions reached a peak of 44,500 per month, and in June, 1948, the horsepower of connected load converted reaches a monthly peak of 116,000 horsepower. Figure 7 shows the "Tentative Schedule of Changes for 60-Cycle Operation," together with the total number of customers to be converted in each geographical area.

Detailed feeder cutover schedules were then prepared for each area and referred to the company's operating department for review and determination of the switching and load-carrying requirements, together with the required transmission and distribution line and station switching sequences. The unprecedented load growth experienced by the company since the cessation of hostilities has necessitated careful planning to co-ordinate the frequency change cutover schedules with the company's distribution and transmission system construction program. The many different operations of the several contractors involved in performing frequency change work has made adherence to the feeder cutover schedules imperative once established; changes in these schedules being made only in emergencies, or when it is found that the frequency change program can be expedited by revising the schedules. Present schedules call for the cutover of 1,151 feeders in 378 separate cuts or an average of three feeders per cut. The number of customers cutover range from one to a maximum of 6,123, with an average of 1,850 per feeder cut. The horsepower of connected load cutover at any one time ranges from approximately 500 to a maximum of 35,310, with an average of 5,430.

Basic Procedures

One of the most important phases of the program is the establishment and control of the flow of the enormous quantity of paper required to co-ordinate the activi-

ties of the various groups involved in effecting the conversion, so that, at the time of cutover of each customer, all of the work necessary for the proper conversion of the customers' equipment to the new frequency has been accomplished. Work flow charts were prepared and used as a base to control all operations of the project. These flow charts show the point of initiation of each item of paper, the action to be taken, the detailed forms to be prepared and processed, the lines of flow for each form, and the final disposition. Early studies indicated the only way in which the records could be practicably and economically handled was by the use of a punch-card and automatic sorting and tabulating machine system. As this was a unique application of tabulating machine operations, the records section had to develop new and unusual methods and procedures. It was determined that the conversion could best be handled by grouping customers into four general classifications:

Class 1—Agricultural power customers having deep-well direct-connected turbine pumps.

Class 2—Industrial customers with a connected load in excess of 50 horsepower.

Class 3—Commercial and small industrial customers with a connected load of less than 50 horsepower.

Class 4—All domestic customers.

Each customer is assigned a frequency change number with 17 digits which identify the customers as to area; the substation source of the feeder from which served; the feeder; the commercial district in which the customer is located; the meter read book; the customer's folio or account number; and the classification of his account. The following illustrates a typical frequency change number:

Area	Substation	Feeder	District
4	07	07	31

Meter Book	Folio	Classification
105	11,211	4

Figure 7. Tentative schedule of changes for 60-cycle operation

* INCLUDES WHOLESALE CITIES

The customer's frequency change number controls throughout the entire sequence of operations. For ready reference in handling customers' telephone calls in the area under conversion, an alphabetical list is prepared for each district, showing the customer's name, address, and frequency change number.

Operations are initiated by transcribing to a machine record card data on each customer from the company's district office records, together with the feeder from which the customer is served. From these data, a master record card is punched and the flow of the necessary paper is commenced. It is estimated that during peak operations, approximately 712,000 cards per month will be processed through the records section with a total of 11,200,000 cards for the project.

Customer records are established 12 months in advance of cutover. This allows four months for the processing of records and eight months for the survey and procurement of materials and the scheduling of the cutover with the customer. After these records have been set up in the records system of the frequency change operations, the local district offices, from which the customer records are obtained, are required to keep the frequency change department advised of any change in status of their customers, with the exception of domestic customers. Because of the relatively large number of changes continually occurring in the moving in and out of domestic customers on the company's system, no attempt is made to maintain the initial records of these customers prior to 60 days before cutover.

Approximately 60 days prior to the scheduled date of conversion, a recheck is made of the district office records of all customers connected to each feeder, and from this date on to the date of cutover, no changes are permitted to be made in the feeder system except under emergency conditions. This lead time of 60 days is maintained so that the mailing pieces outlining the company's program of conversion and the notices of cutover setting forth the date and hour of conversion can be directed to each customer in advance of the changeover and the contractors' forces scheduled to the customer's premises for the conversion.

Pilot Cutover

In order to try out the plan of conversion and to test the procedures developed for surveying and adapting customers' utilization equipment, a small area was isolated from the 50-cycle system and cutover to 60 cycles early in 1946. This in-

volved the cutover of about 4,400 customers with a connected load of 1,008 horsepower. The experience gained from the cutover of this pilot area proved invaluable in developing final conversion plans, procedures and tecaniques.

Connected Load and Number of Items of Equipment Requiring Conversion

Table III shows the connected load of the system together with an estimate of the number of items of equipment to be converted for 60-cycle operation. Included in these items are every type and kind of electrically driven or operated device, ranging from electric clocks to the largest steel mill motor drives. Of the 2,196,800 horsepower of connected power load requiring survey and engineering, 1,390,800 or 63.5 per cent will require conversion; the balance or 36.5 per cent being allowed to go "no change." Of the total number of items of equipment connected to the system, 53.4 per cent will go "no change", with the balance or 46.6 per cent requiring change.

Fundamental Engineering Principles

The application of engineering principles to the determination of the changes required to be made for the adaptation of the many thousands of different kinds, types, and makes of frequency-sensitive equipment and devices for operation at a higher frequency is not an exact science. It is a combination of fundamental theories, judgment, and experience. The engineers responsible for determining the adaptation required to reproduce at 60 cycles essentially the same performance which obtained when operating at 50 cycles have no control over the use, intended use or application of the equipment, or of its mechanical or electrical condition at the time of adaptation and, accordingly, must consider many factors in addition to the theoretical engineering principles involved, in determining the appropriate change. Accordingly, no attempt is made in this paper to discuss in detail the engineering theories involved but only to give a general outline of the basic engineering methods and procedures used in effecting the conversion of a few of the more general classes of equipment encountered in a frequency change program of this magnitude.

The effect of a frequency change on customers' equipment is manifest in various ways for different kinds of equipment, being visible in the case of rotating equipment but generally invisible in the case of nonrotating devices. The most significant and obvious effect on rotating equipment is an increase in speed directly proportional to the increase in frequency. Electrically, a change from 50 to 60 cycles is relatively small and, if it were not for the accompanying speed change, the amount of adaptation required for rotating machines would be materially less. Certain changes occur in the performance characteristics of electrical machines affecting magnetizing current, core loss, power factor, efficiency and torque. In nonrotating devices, the change is apparent only in a change of performance characteristics. It follows from the foregoing, that the principal objective in adapting frequency-sensitive utilization equipment for operation at a higher frequency is to compensate for the increase in speed in the simplest and most economical manner.

For conversion purposes, frequency-sensitive equipment may be divided into three general classes:

1. Equipment connected to the motor through flexible drives of various kinds and types which can be adapted by a simple mechanical change in the drive to maintain the original speed of the driven equipment. This represents about 54 per cent of the total items of equipment requiring adaptation.

2. Equipment directly connected to the motor, representing about 26 per cent of the total items requiring conversion and consisting principally of centrifugal pumps, deep-well turbine pumps, fans, blowers, and similar devices. Equipment in this class can in general be adapted by mechanical changes to the driven equipment, such as trimming or destaging pump impellers, and trimming or repitching fan blades and blower impellers.

3. Equipment requiring adaptation by an electrical change to the motor or driven unit, or a combination of electrical and mechanical changes. This represents approximately 20 per cent of the total items requiring adaptation.

Approximately one year was spent in engineering research to accumulate pertinent data on common and generally repetitive items of equipment and to establish basic adaptation principles, methods and procedures for the use of the several contractors. This was necessary in order to provide uniformity of procedure by the several contractors and to avoid duplication of engineering by these contractors. These data were tabulated and set forth in the frequency change manual, and this manual probably contains one of the most complete listing of domestic and commercial electrically-operated equipment extant.

Table III. 50-Cycle Customers, Connected Horsepower, and Items of Equipment Requiring Survey, Engineering, and Conversion

	Surveyed and Engineered	To Be Converted
Customers		
Agricultural	7,440	7,440
Industrial	30,426	30,426
Commercial	82,134	82,134
Domestic	580,000	580,000
Total	700,000	700,000
Horsepower		
50-cycle industrial and commercial power load	2,196,800	1,390,800
Per cent "No Change"		36.5
Items of Customers' Equipment

Company will adapt		4,600
Customer will adapt		2,650
No change	550	
Meters		
Total number replaced	665,000	
Relagged and tested	374,500	
New meters installed	290,500	

Survey and Engineering Procedures

A field survey is made of each item of frequency-sensitive equipment on customers' premises, on forms provided for this purpose, in sufficient detail for the contractors' engineers to determine the appropriate change to be made. The initial survey of commercial and industrial customers' equipment is made approximately eight months in advance of the date of cutover except in the case of certain special items such as large synchronous motors, large air compressors, and heavy mill drives. These items were surveyed as much as two years in advance of the scheduled cutover date so as to provide sufficient time for the procurement of material and parts. The procurement of material and parts to meet the cutover schedules has been one of the most difficult problems.

From the survey data, the contractors' engineers analyze the make, type, and application of each item of equipment and determine the most appropriate and economical change consistent with recognized engineering and machine design standards. Frequently, electrical or mechanical tests are necessary to obtain information for the engineers' use in determining the proper adaptation, to record the 50-cycle performance of the equipment, and to demonstrate that the 60-cycle

operation essentially duplicates the 50-cycle operation. Such tests include load and performance tests on motors and generators; hydraulic tests of head, capacity, and efficiency on deep well turbine pumps and large centrifugal pumps; and mechanical tests of vibration, air delivery and noise levels. Machines are often found in use in a service for which they were not originally intended by the designer or manufacturer and, in other cases, customers have taken advantage of the increased torque available from a 60-cycle induction motor operating on 50 cycles.

In the large majority of cases, the appropriate change is determined without need of consultation with the manufacturer but, in the case of certain equipment, such as large synchronous motors, motor-generator sets, rotary converters, blowers, pumps, and mill drives, it is necessary to obtain data not obtainable by physical survey in order to compute 60-cycle performance characteristics and mechanical stresses. The manufacturers have co-operated generously in supplying information, but in many instances, manufacturers have had no occasion to determine how their appliances or equipment would perform when operated at other than the design speed or frequency and, accordingly, have been unable to furnish all of the desired information without further engineering development on their part.

As shown in Table III, 53 per cent of the total number of items of customers' equipment in operation on the company's system will operate satisfactorily at the higher frequency without change, provided the equipment is in good mechanical condition. Included in the 53 per cent are small air and refrigerating compressor units commonly found in garages, service stations, butcher shops, and other commercial establishments. Also included are a number of machine tools installed during the war which were standard 60-cycle units and were not modified by the user for operation at 50 cycles.

Electrical Changes

Transformers in general benefit by an increase in frequency. Table IV shows the effect of such a change on distribution and power transformers.

The efficiency of the transformer is usually improved up to approximately normal full-load because the decrease in iron loss exceeds the increase in copper loss. At over-load operation, the efficiency may be slightly less if the increase in copper loss at the higher loads becomes greater than the decrease in iron loss. Constant-voltage type transformers with tuned circuits or saturation characteristics to control secondary output voltage require modification since the output voltage would otherwise be stabilized at a value considerably higher than the rated voltage. In the smaller sizes, it is generally more economical to replace the transformer. In sizes of 1 kva and larger, modification is usually accomplished by removing the proper amount of core iron and changing the value of the capacitance in the tuned circuit.

Induction and synchronous motors are affected by a change in frequency in the same way as transformers. In addition, the synchronous speed is increased 20 per cent and starting and pull-out torques are reduced. Full load efficiency will, in general, remain the same or will increase slightly. Bearing friction and windage losses increase but these constitute such a small percentage of the total losses that they do not importantly affect the efficiency. Power factor will improve because the magnetizing component of the exciting current decreases considerably. In the case of induction motors, the running torque over the normal range of operation is dependent upon the connected load, and the motor will inherently supply the torque required at the expense of increase slip or a reduction in speed. With the same horsepower output after adaptation, the per cent slip at the 60-cycle speed will remain essentially the same as at 50 cycles. For the average general purpose induction motor, the slip is approximately 3 per cent. If the full load running torque required at 60 cycles is the same as obtained at 50 cycles, the per cent slip will increase to approximately 120 per cent of the 50-cycle value.

The maximum torque varies inversely to some power less than the square of the frequency. Computations and tests indicate that at 60 cycles it will be approximately 73 per cent of the 50-cycle torque. Values less than this obtain on very large motors but will generally approach 69 per cent as a limit, whereas values above 73 per cent will in general obtain on the smaller integral and fractional horsepower motors. Although the maximum torque available decreases, in general application this is of no importance since the very high loads required to reach the point of pull-out practically never occur.

Table IV. Per Cent Change in Performance of 50-Cycle Transformers When Operated at 60 Cycles

	Small Transformers $1^1/_2$ to 25 Kva	Medium Transformers $37^1/_2$ to 200 Kva
Iron losses	80–90	80–90
Exciting current	40–60	40–60
Total copper loss	101	103
Impedance	109	115
Regulation 100 per cent power factor	100	108
Regulation 80 per cent power factor	107	111

Starting torques decrease approximately as the square of the frequency and by tests, the 60-cycle value was found to vary between 59 and 65 per cent of the 50-cycle value; the smaller the motor the closer the value approaches 65 per cent. However, as these torques increase as the square of the voltage, they are not reduced below the design torques by the change in frequency to the extent shown above because the company's nominal service voltage is 10 per cent above the standard design voltages of general purpose motors.

Motors must be modified when it is essential to maintain approximately the same speed as obtained at 50-cycle operation or when it is necessary to maintain the 50-cycle starting and pull-out torques. Speed is maintained by reconnecting, rewinding, or repoling to an increased number of poles. Torque is maintained by rewinding with fewer turns and larger wire. In the case of wound rotor or synchronous motors a rewind or reconnection of the stator winding also requires a change in the number of rotor poles.

In the case of synchronous motors driving reciprocating loads such as air or ammonia compressors, consideration must be given to the effect on motor current pulsation. Generally, no significant change in pulsation occurs but occasionally, it is found necessary to change the WR^2 of the fly-wheel. Each case must be individually studied.

The rewinding of a-c machines for an increased number of poles often results in windings with unequal numbers of coils per pole group. Almost all of the practical winding combinations were investigated and catalogued in order that only those resulting in satisfactory motor performance would be used. The major manufacturers have been very co-operative in checking any unusual proposed windings. By the use of such windings, it has been possible to reconnect instead of rewind in many cases, thereby effecting important economies in the cost of motor conversions.

Most motor-generator sets are allowed to increase in speed, changes being made to the d-c generators to obtain the proper output characteristics. The parts of a motor-generator or rotary converter

chiefly affected by increased centrifugal forces are armature bands, wedges, commutators, damper windings, field pole pieces, and pole bobbins. These must be checked carefully to be sure that safe stress limits will not be exceeded. To obtain the data necessary to make the proper modifications and adjustments at the time of speed up, preconversion tests are made, the kind and extent of these tests depending on the size and importance of the unit. In general, additional field resistance is all that is required for the adaptation of generators where regulation or stability is not critical. Machines used in parallel operation or those requiring precise voltage regulation may require a reduction in the cross-section of the magnetic circuit in order to restore saturation and maintain stability. This is usually accomplished by slotting the sides of the main pole pieces, the size of the slot being predetermined by calculations based on test data. Some unique techniques have been developed for carrying out this operation, such as flame-cutting the slots in pole cores integral with the frame of the generator.

Arc welder motor-generator sets constitute a special class. Multiple operator units use constant potential generators and ballast resistors and are adapted in accordance with standard procedures for general purpose motor-generator sets. Single operator units have differential compound characteristics and are readily adapted for 60-cycle operation by the installation of suitable resistors in the various control fields. Values of resistance to be inserted are selected so as to give the same or a slightly higher open circuit voltage as obtained on 50 cycles.

Industrial control devices depend on electromagnetic forces to activate contactors, relays, and valves. The National Electrical Manufacturers Association rates magnetic contactors in ten sizes from 00 to 8. Sizes 00 to 2 and some of size 3 have resistance-reactance ratios such that the loss of pull due to the increased frequency is not sufficient to require correction. The larger sizes are adapted either by the procurement of new coils or by removing 15 per cent of the turns. In critical cases, a tap may be brought out of the coil for 50-cycle operation prior to conversion.

Electric discharge types of lighting such as fluorescent, neon, and mercury vapor lights, of which it is estimated that there are approximately 330,000 of the fluorescent and mercury vapor types on the company's system, are equipped with current limiting ballasts. These ballasts contain a reactor or a combination of condenser and reactor which are affected by a change in frequency. Those using single reactor ballasts such as neon lights and small single lamp fluorescents require no modification. In the larger sizes, however, such as the widely used 2-lamp 40-watt high power factor type, a change to 60 cycles causes a 10 to 20 per cent reduction in current in the lag lamp with a resulting decrease in light output, and approximately a 70 per cent increase in the lead lamp current with a considerable increase in the light output. This causes injurious heating of the ballasts and importantly reduces the lamp-life. New 60-cycle ballasts were unobtainable in the quantities required to meet the conversion schedule, and, as the cost of replacement was high, an adaptor was developed by the department's engineers for use with the existing 50-cycle ballasts to restore the lamp currents to normal 50-cycle values when used on 60 cycles. This adaptor consists of a 3-winding transformer reactor and approximately 50 per cent of the 40-watt 2-lamp fixtures are converted by their use; the remaining 50 per cent being converted by installing 60-cycle ballasts. It is of particular interest that the survey of fixtures to date shows that approximately 40 per cent are equipped with 60-cycle ballasts which have been operating successfully at 50 cycles. Large installations of high intensity mercury vapor lighting were encountered in aircraft plants constructed during the war. Most of these are 2-lamp 400-watt fixtures and are adapted by use of an autotransformer to reduce the voltage across the capacitor together with a tap change on the primary of the ballast transformer.

Mechanical Changes

The largest class of mechanically adaptable equipment other than flexible driven equipment consists of centrifugal and turbine type pumps. It is estimated that a total of 45,000 pumps of various makes and types will be encountered and adapted during the program. This includes refinery process pumps handling acids, propane, crude oil, caustics, molten salt, light fraction petroleum products, water, and sewage.

Theoretically, a 20 per cent increase in the speed of centrifugal and turbine pumps results in a 20 per cent increase in capacity, a 44 per cent increase in developed head, and a 73 per cent increase in brake horsepower. As stated previously, the majority of pumps can be adapted by trimming impellers, if above minimum diameters, or in the case of multiple stage deep-well turbine pumps, by trimming, destaging or both. Theoretically calculated trims could not be used and it was therefore necessary to develop performance graphs of the various types and makes of pumps based upon empirical values and experience. However, caution must be used in applying these graphs as it is often found upon removal of the impeller that wear has taken place and the amount of trim must be modified accordingly.

In four of the major oil refineries, a total of 2,300 pumps have been engineered for change in the foregoing manner. Of this total, only 100 pumps are being replaced because of the impossibility of adapting them to reproduce the same performance on 60 cycles as obtained on 50 cycles.

The problems involved in adapting deep-well turbine pumps, of which it is estimated there are a total of 7,800 on the company's system, are many and complex, being aggravated by changed pumping conditions which have taken place since their initial installation, and in many cases, by receding water tables. The most important factor in engineering the required changes is obtaining accurate test data on the pump's characteristics at 50 cycles. Performance curves when available are obtained also from the manufacturer for each type and size of pump. With these data, it has been possible to determine with reasonable accuracy the change required to reproduce the same head, capacity and efficiency at 60 cycles as obtained at 50 cycles. In many instances, it has been possible to increase the efficiency of the pump. The poor mechanical condition of many deep-well turbine pumps has added also to the problem of pulling, adapting, and reinstalling them for the higher frequency.

Fans and blowers constitute the second largest group of mechanically adaptable equipment. In general, the same engineering principles are employed in adapting them as those used in adapting pumps. High-speed fan or blower impellers frequently require dynamic balancing to insure satisfactory operation at the higher speed after trimming.

Large compressors present a major problem as these units are usually driven by synchronous motors where WR^2 must be taken into consideration. Where it is necessary to maintain the existing compressor capacity, and when the compressor can otherwise be speeded up, they can often be mechanically adapted by either installing shorter disk cranks changing head clearances, installing cylinder liners and smaller pistons or a combination of two or more of the previously mentioned

methods. Where increased compressor capacity is permissible, some large compressors can be adapted simply by the installation of modern valves to replace old-style valves.

Many types and kinds of unusual equipment are encountered such as expellors, attrition mills, hammer mills, electric organs, and so forth, all requiring special consideration in determining the appropriate adaptation. For example, approximately 200 hammer mills, totalling 10,000 horsepower or an average of 50 horsepower per unit, have been encountered. These are usually driven by 2-pole motors designed for 60-cycle operation but the use of these mills varies widely and, where one mill can go "no change," a similar mill used for a different purpose must be adapted to maintain speed.

Many unusual electrical and mechanical problems have been encountered in the project requiring considerable ingenuity on the part of the engineers, however, space does not permit of detailing these problems and their solutions.

Survey and Conversion Procedures

The assignment of customers' equipment to the contractors for survey and conversion is made by classification of the account, namely: domestic, commercial, industrial and agricultural having direct-connected deep-well turbine pumps. Electric railways are handled separately as a special assignment.

The procedure followed in the survey and conversion of each class of customer differs with each contractor, and for this reason will be set forth separately hereinafter.

Each contractor operates as an independent contractor but under the direction of the frequency change department for co-ordination of the work and to assure uniformity of policy. Items of equipment which are common to all customers, such as timing devices and fluorescent lighting, are reassigned to the contractor performing that phase of the conversion. As an example, when the survey men of the domestic contractor find timers, home workshop equipment, small domestic pumps, incubators, and other equipment of a specialty nature on the domestic customers' premises, this equipment is reassigned to the appropriate contractor for engineering and conversion. The domestic contractor is employed to perform the conversion of household appliances only, and is not equipped with the materials or the craftsmen necessary to perform specialty work. This plan of reassignment of specialty items of equipment has been highly satisfactory and has eliminated duplicating stocks of materials and craftsmen having special skills, in each of the contractor's organizations.

The company maintains 26 district offices throughout the territory being cutover to 60 cycles for the conduct of its regular business, and as the frequency change operations progress throughout the areas of conversion, the field organization of the frequency change department and its contractors establish field headquarters in each district. This is done so that a close relationship can be maintained between the district office and the frequency change personnel in all matters concerning customer relations, and the handling of telephone inquiries from the customers. Clock depots are located also in each district for the convenience of customers in cycle changing or exchanging portable clocks. As a result of the continually moving operations, it is necessary to provide office, clock-exchange, and headquarters building space for the frequency change operations of the department and its contractors and, when working more than 25 miles from headquarters, to provide transportation and hotel accommodations for the men.

Domestic Customer Conversion

Frequency-sensitive appliances of approximately 580,000 domestic customers will be cut over during the project. This represents 83 per cent of the total customers involved.

The domestic contractor receives his survey assignments on prepunched and printed tabulating cards showing the name, address and frequency change number of each customer. On the reverse side of the card, there is printed a list of appliances generally found in the home. These cards are assigned to survey crews who list the items of appliances found on the customer's premises, such as washing machines, refrigerators, record players, and so forth, and as they are surveyed, a printed tag is placed on each item of equipment designating whether or not a change is required. At this time, the customer is also advised of the details of the program, the date of cutover, and the approximate time the conversion crews will call at the customer's residence to adapt the frequency-sensitive appliances designed. The survey is made approximately three weeks in advance of the date of cutover and because of the relatively short time to cutover, the survey man (in the course of conversation with the customer) changes the bushings on record players having this type of drive. From the master inventory card prepared by the survey man, a separate conversion card is made out for each appliance requiring change showing the make and model and the materials required for the change. These cards are then assigned to the conversion crews for the adaptation of the appliances, a few days in advance of the date of cutover.

The domestic contractor conducts his field operations from mobile trailer units which are moved into each district as the conversion progresses. Each field unit is self-contained with office trailers for the supervisory personnel, warehouse trailers, and portable shops.

All appliances are adapted in the home with the exception of gear driven washing machines and gear driven record players which are transported to the portable shops for conversion.

The domestic contractor employs approximately 184 men, of which 66 are on survey and 83 on conversion, the remainder being supervisory and clerical personnel. Experience to date in the conversion of domestic customers shows that 40 per cent of all customers in this class have frequency-sensitive devices requiring adaptation. The survey of domestic customers is currently being made at the average rate of 28 customers per survey man day, and conversion at the rate of 8 customers per man day.

Commercial Customer Conversion

The 82,134 commercial customers having a connected load of less than 50 horsepower comprise approximately 11.7 per cent of the total number of customers to be cut over, with a connected load of approximately 114,000 horsepower.

Included in the commercial classification are restaurants, markets, service stations, small machine shops, doctors, dentists, and other types of small business establishments.

A large majority of the equipment encountered in this class is repetitive and the methods of conversion are set forth in the data book section of the frequency change manual. However, certain equipment, such as walk-in type refrigerating units, medium size compressors, and certain machine shop tools require separate engineering and procurement of materials. Accordingly, all commercial customers are surveyed approximately three months in advance of the date of cutover.

Since a large percentage of the equipment encountered in this group is driven by single phase motors, special single

phase crews have been organized to make starter spring changes when required. While theoretically, a large proportion of the single phase commercial refrigerating units could go "no change," experience has shown that this equipment is operated with little maintenance and, on speed up, would not transfer from the starting winding to the running winding. As a result, in order to avoid equipment failures and food spoilage, the policy has been adopted of maintaining 50-cycle speed by changing the driven pulley on practically all commercial refrigeration units and changing the setting of the transfer switch on the starting winding of the motors.

Also found in this group are special timing devices, such as time stamps, bank check recorders, X-ray timers, diathermy timers, hospital timers, police and fire station timers, photographic timing equipment, and so forth, much of which must be converted simultaneously with the feeder cutover. These items are handled by special crews of the clock contractor and are given priority of conversion on the day of cutover. All nonportable clocks are adapted on the customer's premises but the portable clocks are required to be brought into the clock depots for exchange or cycle-change, as hereinafter discussed.

Industrial Customer Conversion

The industrial group having a connected load in excess of 50 horsepower comprises approximately 30,426 customers or 4.3 per cent of the total, with a connected load of 1,619,288 horsepower or 82 per cent of the total connected load to be cut over. The engineering determinations and the procurement of materials require that the survey be made at least eight months in advance of the date of cutover.

Customers in this class are personally contacted by one of the department's commercial division employees in company with a representative of the contractor. At this initial contact, the frequency change program is explained arrangements made for the contractor to survey the equipment. Since in many industrial plants the shutting down of a piece of equipment for survey may interrupt the customer's manufacturing or processing operations, every effort is made to plan and schedule the survey so as to provide the minimum interference with the customer's operations.

Data obtained by the contractor's survey men are processed through the contractor's engineering division and the proper method of adaptation determined. Items of equipment involving costly or unusual changes are referred to the engineers of the frequency change department for review or assistance in determining the propriety of the changes. When the final determination has been made on all items of equipment in a customer's plant, the customer is then advised of the proposed changes and arrangements made for the out-of-service time required for adaptation.

The preponderance of equipment in the average industrial plant can be preconverted with only a few of the more critical items requiring simultaneous change with the cutover of the feeder. Where it is found impossible to take out of service a critical item of equipment, a temporary frequency changer is installed and the conversion postponed for a more favorable time. While most of the changes in industrial customers' equipment can be performed by reasonably competent electrical or mechanical craftsmen, the contractors found it necessary to train their foremen and field supervisors in the handling of emergencies and unusual conditions which inevitably arise in a program of this size. The field operations of the contractors are carried out from a main field headquarters located in each area and subfield offices located in trailers, each of the latter generally consisting of a warehouse trailer, a small repair shop, and a portable construction house for the clerical and supervisory personnel. Any complaints arising after cutover are handled by trouble crews especially trained for this purpose.

Agricultural Customer Conversion

Agricultural customers comprise approximately 7,400 customers or 1 per cent of the total, with a connected load of 252,537 horsepower or 12.3 per cent of the total power load to be converted.

Approximately six months in advance of the cutover, a representative of the company calls on each agricultural customer to outline the conversion program and the method of adaptation employed by the company in adapting deep-well turbine pumps. At this time the customer is offered the option of an allowance in lieu of conversion should he prefer to have his own well contractor perform the work or, if he elects, the company will adapt the pump without cost with their own crews. As is shown in Table III, approximately 34 per cent of the customers elect to accept the allowance in the amount of the company's cost so that they can perform repairs or modernize the pump when removed from the well for adaptation. If the customer elects to have the company make the adaptation, the customer is advised that a hydraulic and electric test will be made on the pump so as to establish the 50-cycle pump characteristics necessary for determining the adaptation for the 60-cycle speed. After the tests have been completed and the method of conversion determined, the customer is again contacted, given a summary of the tests, and advised of the proposed method of conversion.

Since the output of a deep-well pump is in part dependent on the draw-down of the water during the pumping cycle and in part on the operating head, which may often be varied by the operation of valves, every effort is made to obtain accurate data at the time of tests as to the standing water level, draw-down during operation, horsepower consumption, output at various heads, and any other data which will assist in making the proper engineering determinations.

The pulling, adaptation, and reinstalling of deep-well turbine pumps is handled by crews trained by the department. These crews are equipped with 20 light-duty and 5 heavy-duty mobile pump-pulling rigs especially constructed in accordance with specifications drawn up by the department's engineering division. The crews operate out of field headquarters, at which mobile machine shops are located, together with the necessary supervisory and clerical staffs. Pump bowls are brought to the portable machine shops for trimming and/or destaging, and any defective parts are called to the customer's attention in order that he may have them repaired or replaced if he so desires. A large majority of the customers take advantage of this opportunity to put their pumps in good operating condition.

Occasionally pumps are found to be stuck in the well and, after making a reasonable attempt to pull them, the company then offers to either install an offset V-belt drive or to give the customer an allowance in lieu of conversion equivalent to the cost of such an installation. Offset drive heads have been designed by the engineering division and are manufactured locally according to the company's specifications. At the peak of operations, the pump conversion section of the department had a total of 117 employees engaged in adapting deep-well turbine pumps.

Electric Railways

The two railway systems served by the company have connected loads of approximately 151,000 horsepower, mainly in

Figure 8. Mobile mercury arc rectifier substation

Showing from left to right: Harmonic filter, rectifier house, heat exchanger, main transformer, transformer cable pothead rack, auxiliary control switches, auto transformers, and oil circuit breakers

motor-generator sets and rotary converters ranging in size from 400 to 1,500 kw. Each of these companies owns and operates their own distribution system which are fed from a number of points of delivery from the company's system. The two systems include 63 substations with 77 motor-generator sets, 32 rotary converters, and 6 mercury arc rectifiers. Of the 77 motor-generator sets, 25 are driven by synchronous motors.

Conversion of the railway units offered a number of problems, not the least of which was the necessity of constructing two mobile d-c substations to replace temporarily the units as they are removed from service for adaptation.

One of the mobile stations consists of a 1,400 horsepower 2,200-volt synchronous motor direct-connected to a 1,000-kw 600-volt d-c generator with associated controls, all mounted on a rubber-tired trailer for outdoor use. A second trailer carries a bank of three 333 kva 16.5/2.3 kv transformers with oil switch and disconnecting switches.

The second mobile unit consists of a General Electric 6-phase 12-tank mercury arc rectifier rated at 2,400 kw with a control cubicle for 50 and 60 cycles, anode and cathode circuit breakers, and their required controls, all mounted in a weatherproof housing on a rubber-tired tailer. A second trailer carried a 4,500-kva 3-phase to 6-phase 11,500/611-volt transformer and auxiliaries, and a heat exchanger for the rectifier.

The rectifier and transformer were obtained from a War Assets plant where one transformer supplied two rectifiers, hence the reason for the oversized transformer. Because the voltage of this transformer does not conform to the voltage of the railway distribution system, a bank of 3-phase autotransformers rated 16.5/11.5 kv is mounted on a third trailer. This trailer carries also the necessary oil circuit breakers and disconnects. This mobile rectifier substation is somewhat unique and is believed to be the only one of its kind. Used also in connection with the railway conversion are two sets of load boxes mounted on trailers with variable taps to allow a wide range of current values. Figure 8 is a picture of the portable rectifier substation equipment lined up outside of one of the railway substations.

As the railway distribution systems are served at 17 points of delivery, it was necessary to plan the conversion of the two systems concurrent with the conversion of the company's system at the various feed points. The co-ordination of the conversion of the two railway systems with that of the company's main system, and the transporting, connecting, and disconnecting of the portable substations has required careful planning and scheduling by both the railways and the company.

Conversion of Electric Clocks and Timing Devices

It is estimated that approximately 350,000 electric clocks and timing devices will require adaptation for operation at 60 cycles. Since the advent of electric clocks, a number of the early or small manufacturers discontinued the manufacture of clocks which made it impossible to obtain replacement parts and, therefore, the company established an exchange plan whereby the customer has the option of having his clock cycle-changed without cost or to exchange his clock for a new and modern one with a small cash payment. The clocks being used for exchange purposes are Telechron Incorporated and General Electric Company.

Customers are required to bring portable clocks for cycle-change or exchange to conveniently located clock depots in the area under conversion.

A majority of the timers used for gas and electric ranges are built into the range and are adapted on the customer's premises by the clock contractor's field crews. If the range timer is obsolete and parts are not obtainable, the customer is offered a replacement timer.

The use of electric timing devices for the precision control of processes has grown tremendously in the last ten years, and many special applications have been encountered. In most cases, the frequency-sensitive component of these timing devices is a standard clock type synchronous motor with a rating of one or two watts and its adaptation for 60-cycle operation consists in general of changing the clock rotor. Arrangements are made with the respective manufacturers to adapt the special and critical timing devices. The handling of the conversion of clocks and timers is a sizable project itself and, at the peak of the program 155 men were employed by the department and the clock contractor for this phase of the work.

Conversion of Meters

As all watthour meters are frequency-sensitive, it is necessary to either replace or adapt approximately 665,000 50-cycle meters on the company's system as well as a number of customer-owned meters. It had been originally planned to retire 275,000 obsolete-type meters during the program. However, difficulty in obtaining delivery of the required number of new meters made it necessary to substantially modify this program, thereby adding importantly to the number of meters to be relagged. A special meter division of the frequency change department was established to handle the replacement or removal, relagging, and reinstallation of all frequency-sensitive meters. Trained meter men in the number required were not available and it was necessary to carry on an intensive training program in order to obtain the required complement of men. Meter conversion is divided into two major operations, namely, field operations or the replacement of the meters on the customer's premises, and relagging and repair operations which are performed at a central shop on a two-shift basis. Special meter test tables were designed and constructed for this work.

Information concerning the customer's meter is secured at the same time that the customer's record is picked up in the commercial district office, approximately one year in advance of cutover. This information includes the type, code, year set, mounting, customer's frequency change number, and the name and address of the customer. The information thus obtained is punched in a tabulating card which is used as an order by the meter division for replacing the 50-cycle meter. The meter setter fills in on the card the meter number, code and reading of the 50-cycle meter before it is removed, and similar information for the 60-cycle meter installed, and the card is then returned to the records section where tabulated lists are prepared and forwarded to the stores and accounting departments and the district commercial offices of the company.

Integrating meters are changed approximately 45 days in advance of cutover, except in the case of large power meters which, together with demand meters, are replaced simultaneously with cutover. Field operations are carried out from temporary field offices.

At the peak of operations, 152 men were employed in the meter division.

Transportation

The work of converting customers' equipment extends over a service area of approximately 18,000 square miles and the problem of transporting equipment, materials, and employees, and of housing the employees in the more remote areas is one of considerable magnitude. When physical operations were commenced in 1946, automobiles and trucks were difficult to procure. At the peak of operations, there were approximately 344 passenger cars, 388 trucks, 12 office-type trailers, 58 miscellaneous trailers, and 153 personally-owned cars used under operating agreements, or a total of approximately 953 motor vehicles in use by the department and its contractors. This equipment has traveled as much as 771,000 miles in one month.

Equipment and Material Pools

In order to facilitate the adaptation of customers' equipment and at the same time provide equipment for emergency service during conversion, it was found necessary and economic to establish equipment and material pools consisting of special mobile or portable equipment motors, and pulleys for the use of all contractors under the administration of the frequency change department. The equipment pool contains the equipment shown in Table V.

In addition to the foregoing, the pool contains distribution transformers of single and 3-phase types ranging in size from 100 to 1,200 kva each. The frequency changers are designed to provide frequencies of 50 and 60 cycles and voltages of 120 to 480 volts. The principal use of the equipment pool is for the preconversion and postconversion of critical items of equipment in industrial plants, and to provide emergency service at 50 or 60 cycles as required. The two 1,000-kva frequency changers are used primarily for supplying 50 or 60-cycle energy to the two railway systems during the testing and conversion of their substation equipment and to motion picture studios during the conversion of their motor-generator sets.

The motor pool consists of 800 motors of various sizes, speeds and voltages, ranging in size from fractional and integral horsepower single-phase motors to integral horsepower 3-phase induction and synchronous motors from 1 to 800 horsepower. These motors are used as replacement motors in the event of emergency or for temporary replacements during the time the customer's motor is out for rewind or reconnecting.

The pulley pool consists of approximately 20,000 items of various types, sizes, widths, and diameters of pulleys made up of cast iron, split steel, and pressed paper; together with single and multigroove sheaves of various kinds and types. All pulleys and sheaves removed from the customer's equipment are processed through a small machine shop set up in conjunction with the pool stock, and placed in first-class condition for reuse.

Customer Relations

The maintenance of customer relations in a program of this kind is highly important and involves the co-operation and complete understanding of the objective by all parties concerned. Where heretofore the company's operations normally stopped at the meter, the operations of cycle changing customers' equipment commence at the meter. This involves many problems never before encountered by the company and required the development of new policies and procedures entirely unrelated to the normal operations of the company.

Recognizing that many situations would arise in adapting customers' equipment which not only involved the technical aspects of converting hundreds of thousands of items of equipment but also that of entering the homes, offices, business establishments and plants of over 700,000 customers to perform the work, the frequency change department organized to handle all customer relation problems with its own personnel.

Approximately 30 days in advance of the cutover of feeders in a district, the department opens a frequency change office, staffed with personnel to receive customer calls and to handle customer relation problems arising in connection with the work. This office remains open 60 days after cutover of the last feeder in the district, for by that time the customer relation problems have diminished to the point where the regular district personnel can handle the few remaining problems, with occasional assistance from the frequency change department.

While the problems encountered in changing the frequency of a system of this magnitude are many and the costs large, the project is being completed on schedule and, it is believed, to the satisfaction of the many customers of the company as evidenced by the many expressions of appreciation received.

Table V

Quantity	Equipment	Size
53	Frequency changers, kilovolt-amperes	11/2 to 1,000
2	Gasoline-driven single phase alternators, kilowatts	10 kw
4	Diesel-driven 3-phase alternators, kilowatts	15 to 20
6	Direct current motor-generator sets, kilowatts	1 to 1,000
1	Direct current rectifier, kilowatts	2,400
2	Portable substations, kilovolt-amperes	3,000
5	Diesel-driven air compressors, cubic feet per minute	315
5	Water tank trucks, gallons	300 to 1,50

Discussion

T. M. Morong (Southern California Edison Company, Los Angeles, Calif.): The subject paper, because of the extensive nature of the project, could not go into any appreciable detail concerning the various phases of its major activities. Therefore, it is intended to supplement that portion as related to the electrical engineering section's activities in converting customers' equipment. When you consider that the equipment of the customers connected to our lines includes practically every type of electrical apparatus ever designed and in addition is applied to almost every known type of utilization apparatus and process, it be-

Table I. D-C Machine Conversion Estimated for Complete Project

No change and adjust after cutover	676
Resistor addition	786
Rheostat blocking	60
Pole notching	243
Armature rebuilding	64
Motor rewind or reconnect	64
Belt drive installation	3
Pulley change	205
Rectifier installation	5
Purchase new generator	2
Change shims on main poles	16
New rotating element	5
Total	2,129

comes apparent that here again this phase of our activity would require several volumes of books to cover the common types of apparatus encountered.

In order to make economical and satisfactory customer conversions, it was necessary to investigate means of simply modifying the apparatus to give essentially the same operation as previously enjoyed on 50 cycles. Once the actual conversion of customers' equipment was started in the fall of 1945, another general phase of activity commenced, that of advising our customers how to purchase and, where necessary, to modify new 60-cycle equipment for temporary operation on 50 cycles, the reverse of our usual procedure.

Further activities of the electrical engineering section includes development on existing designs, performance testing, checking mechanical stresses of rotating machinery, cost comparisons of alternative methods of conversion, and extensive studies of customers' unusual, and in some cases, highly confidential processes of their utilization equipment. The apparatus involved covered those such as appliances used by domestic customers, commercial customers' equipment as found in hospitals, stores, restaurants and office buildings. Industrial installations such as steel mills, cement plants, refineries, rubber mills, glass factories, automobile assembly plants, in fact about every known type of manufacturing plant, agricultural equipment consisting mainly of deep-well pumps, electric railway substations' large rotating apparatus, and communication apparatus in telephone, radio, and television stations.

It is readily discernible from such broad activities that it is impossible to impart to you any detailed information. There follows, however, a few salient points of a general nature which will give you a brief over-all resume of the conversion of motors and d-c motor generator sets.

As pointed out previously in the subject paper, a large number of motors are able to operate on 60 cycles without change to the motor because of the nature of the application permitting, and a considerable number were already an integral part of 60-cycle apparatus being operated by customers on 50 cycles. In fact, the general approach to all appliances such as domestic refrigerators, washing machines, and so forth, was to allow 90 per cent of those to go no change and the other 10 per cent to have a mechanical drive change.

As a result of this procedure, an estimated total number of 900 motors will be rewound because of burnout, based on records to date, of a most insignificant figure of $^1/_{10}$ of one per cent. The causes of burnouts in most cases have been due to poor maintenance of the equipment requiring an excess of torque over that which the motor is capable of producing and in some cases because of a change made initially in the starter spring for 50-cycle operation.

A total of more than a half million of induction motors is estimated to be connected by commercial and industrial customers to the company lines of which it is estimated a total of 3,700, or less than one per cent, will require rewinding or reconnecting for torque or repoling for speed change. Only 250 new motors will have been installed by the end of the project.

A total of 475 synchronous motors have been surveyed, of which 308, or 65 per cent, were allowed to speed-up, 59 or 12 per cent repoled, 77 or 16 per cent with a new rotor furnished, and 15 new motors or 3 per cent of the total.

It is quite significant from the foregoing figures that very little 50-cycle equipment cannot be modified to operate satisfactorily on 60 cycles. In fact the few cases where new motors were supplied, in many instances the customer desired increased horsepower and paid for the additional plant improvement, and in other cases, it was more economical to purchase new motors because of obsolescence of dies, and so forth, to make replacement parts.

In conclusion, a breakdown of the conversion of d-c motor-generator sets other than welding sets is given in Table I of the discussion to indicate the various methods by which this is being accomplished.

Electrical Developments in the Pulp and Paper Industry

R. R. BAKER
ASSOCIATE AIEE

THE EFFICIENT GENERATION and distribution of electric energy, as well as its effective utilization, is essential in the operation of the pulp and paper mills of the United States. Careful consideration must be given to developments in electric equipment which permit of the most efficient overall plant operations. In the year 1947 it is estimated that the pulp and paper industry used some 14,000,000,000 kilowatt-hours in producing approximately 21,000,000 tons of paper. In the year 1945, the last year for which complete figures are available, among other major industries in the United States, the pulp and paper industry ranked first, in power per ton of product (700 kilowatt-hours), third, in installed generating capacity (1,348,000 kw), fourth, in total kilowatt-hours (11,450,000,000 kilowatt-hours).

The actual power requirements vary for the different grades of pulp and paper as well as for the different operating conditions encountered in mills producing similar grades. From operating results in various mills, it is estimated that the average mill load in horsepower per ton daily production is approximately as shown in Table I.

The per capita consumption of paper products is higher in the United States than in any other country in the world. Statistics indicate a daily consumption of approximately 0.85 pound per individual. This high daily consumption is undoubtedly due to the wide diversity of paper uses. Paper which was originally used for printing almost exclusively, now has a multitude of other uses, such as building papers, wrapping and bag papers, towelling and tissue, boxboard and container boards, drinking cups and food containers, as well as a host of others. To meet the demands of this ever expanding market it has been necessary for the industry to convert from a hand craft to a highly mechanized industry. Each craftsman in the modern plant requires an investment of more than $18,000 and utilizes some 15 horsepower in power-driven equipment in producing approximately 800 pounds of finished paper per day.

Due to the many inherent advantages which electric energy affords in power generation, distribution and utilization, it has been almost universally adopted by the pulp and paper industry as its source of motive power. It is estimated that the industry is some 88 per cent electrified. This form of energy may be developed at the point of greatest economy. It may be transmitted long distances with only slight losses, to a mill site which may be located most suitably for converting the raw materials into the finished product. Electric power distribution presents no serious problems and the mills may be laid out without other consideration than that of the most economical conversion of the raw materials. The many different operating characteristics available in the modern a-c and d-c motors together with the features of either manual or automatic control permit economic operation of all power driven equipment throughout the mill.

Table I

Pulp	Horsepower
Chemical, all grades	7.5–15
Ground wood	50–75
Paper—Exclusive of Pulp Preparation	
Paperboard	15–20
Newsprint	15–20
Book	20–35
Kraft	20–35
Glassine	40–50
Bonds	50–60

Typical Plant Requirements

The modern mill requirements include motors from fractional horsepower, for small auxiliaries, to motors of 3,000 horsepower capacity for driving the magazine grinders required in the production of ground wood pulp. The motors may be arranged for direct connected, geared or belted service with horizontal or vertical mounting and for location on the floor, wall or ceiling. Depending on their location and surrounding conditions the motors may be supplied open, semi-enclosed, splash and dripproof, totally enclosed fan-cooled, or totally enclosed forced ventilated. An idea of the motor requirements of a modern mill can be obtained from a recent electrification in a balanced kraft pulp and paper mill having a daily capacity of 600 tons of pulp and paper. The installed motor capacity in this plant is 23,000 horsepower. Power for this plant is provided by 15,000 kw in turbo-generator capacity, which is equivalent to 75 per cent of the installed motor capacity. The motor list includes some 344 induction motors representing a total of 12,300 horsepower ranging in capacity from 1 to 250 horsepower, and some 32 synchronous motors totalling 10,700 horsepower.

Power Generators

The pulp and paper industry in the United States produces the major portion of its total energy requirements and purchases only a minor portion from local utilities. Statistics for the year 1946 indicate that this industry produced 70 per cent of its total requirements as compared with a national average of only 30

Paper 48-115, recommended by the AIEE general industry applications committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 30, 1948; made available for printing February 16, 1948.

R. R. Baker is with the industry engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. 250-ton balanced kraft pulp and paper mill

Power is generated and distributed at 2,300 volts. Bleeder-type turbines serve to generate power as a by-product of the process steam

per cent. This situation is undoubtedly due to the fact that in this industry large quantities of power can be generated as a by-product of the steam required for process purposes. To produce each ton of paper requires in addition to 700 kilowatt-hours, from 10,000 to 20,000 pounds of steam at pressures from 25 to 150 pounds per square inch. With boiler plants in the modern mills, operating at steam pressures of 600 pounds per square inch and above and steam temperatures of 700 degrees Fahrenheit and higher, the industry is able to generate a large part of its power requirements as a by-product of the process steam. These possibilities have led to the development and extensive use of the bleeder-type turbine in the industry. Depending upon the operating requirements, these turbine units are designed for either single or double pressure bleeding and for either condensing or noncondensing operation. Units ranging from 1,000 to 10,000 kw capacity are installed. In addition to steam power generation in localities where low-cost water-power sites are available, power is frequently generated at these low-cost sites and transmitted to the mill over high-tension transmission lines.

Sixty cycles appears to be the accepted frequency in the modern mill. Power transmission lines are operated at various voltages, 6.6 and 13.2 kv being quite common. In the modern mill, power is generated at a voltage consistent with plant size and concentration of power as well as with the distribution and motor requirements. 2,400 volts is frequently specified however, with large generating units, and a high concentration of power both 4,150 and 6,900 volts have been used. In plants where the power is generated at 2,400 volts, motors 100-horsepower capacity and over are usually selected for this voltage. Where these motors are required for jogging service necessitating frequent starting and stopping, the use of airbreak contactors for the control are recommended.

Power Distribution

Power distribution is an important consideration in the layout of the modern mill. Power driven equipment is located in numerous rather widely separate areas and it is necessary to provide both high and low voltage power service to each of these areas. It is quite common practice to extend one or more feeder circuits from the central power plant to each of the areas. Power is distributed at the generator voltage and is directly applied to the larger motors at this voltage. Power transformers selected for indoor service and of proper capacity to meet the load demand of each particular area, serve to reduce the voltage for application to the smaller motors. Dry-type transformers provide dependable service for the atmospheric conditions characteristic of pulp and paper mills. Such transformers have a somewhat lower installation and maintenance cost than the conventional oil insulated transformers.

The industry has been quick to recognize the merits of factory built metal-clad switchgear for the important function of power distribution. Such equipment can be properly installed at low cost. The features of this type of switchgear assure safe continuous operation with a minimum of outage time for inspection and repair. Metal-clad switchgear is available for any of the established distribution voltages with either oil or air-break switches, and for either light or heavy duty depending upon the plant capacity and the possible fault currents. Light duty gear is suitable for 25,000 and 50,000-kva interrupting capacity and the heavy duty gear for 100,000 to 500,000 kva. The use of this modern metal-clad switchgear with either draw-out or vertical lift circuit breakers affords maximum safety and assures minimum installation and operating costs.

Many of the mills recently built or now under construction are specifying control centers for both high and low voltage motor control. These factory-built control centers provide power bus, disconnecting switches, electrically operated motor control and both circuit and motor protection. With this arrangement the control may be located at some distance from the motor which it serves and the control functions obtained by means of push button or master switch conveniently located adjacent to the motor. This arrangement permits removing the control from congested manufacturing areas and placing it in areas where it may be properly protected against the adverse

Figure 5. Two power centers typical of units installed in the modern paper mill

Each unit includes a dry-type transformer, high-voltage disconnect switch and low-voltage feeder air circuit breakers

atmospheric conditions frequently encountered in pulp and paper mills. The segregation and grouping of the control possible with these control centers permits the establishment of comprehensive maintenance schedules which are essential to continuous, trouble free, efficient plant operation.

In specifying either the high or the low voltage control centers due consideration must be given to the possible fault currents to be encountered. The recent development of the current limiting fuse for use in conjunction with 2,300 and 4,160-volt motor control has increased the interrupting capacity of this control to 150,000 kva on 2,300 volt service, and 250,000 kva on 4,160-volt service. Fault currents on the low voltage service are usually limited by the reactance of the transformer in the power center serving the area. Such transformers usually do not exceed 1,500 kva capacity and therefore serve to hold faults within 50,000 kva.

General Purpose Mill Motors

Although the industry uses many motor drives which have been designed to meet the special requirements of the individual application, a large part of the total installed motor capacity and by far the largest number of motor units installed in the mills are of the standard squirrel cage induction type. These motors range in rating from fractional to perhaps 200-horsepower capacity. They drive such equipment as pumps, screens, conveyors, and agitators. The control for these motors ordinarily consists of magnetic full-voltage starters providing only "start and stop" control functions. These motors are required to operate 24 hours per day, frequently six and sometimes seven days a week. To a large degree the plant performance is dependent on the uninterrupted operation of this important group of motors. To insure good plant performance such motors must be provided with all necessary protective features such as enclosures, winding insulation motor mounting, and so forth, to meet the operating conditions. These motors must also be carefully maintained to permit continuous uninterrupted service.

Synchronous Motors and Plant Power Factor

By the application of synchronous motors with leading power factor to cer-

Figure 9. Totally enclosed fan-cooled induction motor connected to a pulp thickener through integral gearing

tain drives throughout the mills it is possible for pulp and paper mills to maintain high over-all plant power factor. Synchronous motors are frequently applied to many of the motor generator sets as required for power supply on adjustable speed motor drives, to Jordans and vacuum pumps, to chippers and to grinders. The high operating plant power factor resulting from the proper application of synchronous motors relieves the generators, transformers, switching equipment, and feeder circuits of out of phase current, and thus increases the effective capacity of such equipment.

Electronic and Rotating Regulators

Many developments have recently been made in motor and control equipment for application in the paper industry. These developments include among others, improvements in automatic control and regulating equipment, through the introduction of electronic devices and rotating regulators to meet the more exacting regulating requirements. Although sectional paper machine drive has been an accepted standard for many years, recent developments have improved the reliability and the performance of this equipment.

Fundamentally, a sectional electric paper machine drive includes direct current motors for driving the individual sections of the paper machine, a power set for converting from alternating to direct current and for supplying power to the section motors, control permitting independent operation of the individual sections, and section speed regulating equipment providing for an accurate maintenance of the relative speeds of the various sections of the machine required for the proper formation of a continuous web of paper.

With the modern sectional electric drive the older forms of mechanical differential regulators have been replaced with electronic regulators. As supplied by one manufacturer, this electronic regulator consists of several basic elements. These basic elements include a master a-c reference bus, individual section reference a-c tachometer generators, and individual electronic regulating elements including a vacuum tube mixer circuit, a 2-stage vacuum tube amplifier circuit, and a grid-controlled thyratron rectifier field supply circuit. These new electronic-section speed regulators provide the features of field forcing and antihunting essential to high-speed response. They have an infinite number of regulating points and provide increased sensitivity and stability with a broader control range than former types. After initial adjustment these electronic regulators require nothing more than routine inspection and an

Both the electrical design and heavy mechanical construction of the motor contribute to low-cost high quality chip production

occasional tube replacement to maintain top-notch performance.

The modern sectional electric drive may include a power set with a single main d-c generator for supplying power to the section motors or it may include individual generators for each independent section of the machine. With the single generator the electronic regulators are arranged to control the section speed by control of the excitation of the individual section motors. On the other hand, with multiple generators the regulators control section speed through control of the excitation of the individual generators. Figure 14 shows the arrangement of the regulating equipment when applied with the single generator and Figure 15 when applied with multiple generators.

The auxiliary or helper drive is an extension of the sectional drive principle. D-c motors are applied to certain auxiliary sections of the paper forming machine such as the molds and primary presses of cylinder machines, the primary couch roll, wire return roll and dandy roll of Fourdrinier machines, and top main press and dual press auxiliary rolls on both types of paper machines. Where these auxiliaries form a part of a complete sectional electric drive, the motors are operated in parallel with the main section d-c motors and no further provision is re-

Figure 13. In conjunction with sectional electric drive these eight electronic speed regulators provide precision control of the individual sections of this paper machine

Figure 17. Rototrol saturation curve and armature circuit resistance line illustrating the principle of operation of these units

quired for synchronizing their operating speeds with the balance of the machine. Where the auxiliary drives are applied to paper machines equipped with line shaft mechanical drive, it is necessary to provide a d-c generator which is operated at a voltage proportional to the operating speed of the machine for synchronizing the operations of the auxiliaries with the main drive. The synchronizing generator may be driven from the line shaft or it may form part of an auxiliary power set. These auxiliary drives materially improve the quality of the paper through better formation. They also reduce operating costs through improved felt or wire life and by more effective water removal on the forming end of the machine.

Rotating Regulators

The Rototrol, a form of rotating regulator as supplied by one electrical manufacturer has been extensively employed by the industry because of the advantages it affords in the automatic control and regulation of many of the functions required of the power driven equipment. The Rototrol is similar in design to a standard quick response d-c generator. It has a number of independent field windings which are energized in various ways depending upon the regulating problem. These windings include the pattern, pilot, and self-energizing fields. The pattern field normally sets the pattern for the results to be obtained by the regulator. The pilot field provides a means for measuring the operating results produced by the regulator and comparing these results with the prescribed pattern. The pattern and pilot fields are normally connected differentially and any net difference in the field ampere-turns produces a highly amplified corrective action on the part of the Rototrol to reduce this difference. The self-energizing field is usually connected in series with the armature of the Rototrol and the design is balanced so that the voltage produced by the current in the self-energizing field is just sufficient to overcome the total *IR* drop in the armature circuit. In other words, the *IR* drop line for the armature circuit and the saturation curve of the Rototrol coincide. This is possible when the generator is operated at voltages below the knee of the saturation curve. Figure 17 shows the Rototrol saturation curve and the armature circuit resistance line with the tuning resistance set slightly higher than for maximum amplification to illustrate the principle of operation.

Rototrol presents no more of an operating problem than the ordinary d-c exciter. It is provided with air gaps which are comparable with the standard d-c machine. The brushes are standard commercial sizes and are operated at low-current densities. Not less than two brush arms per polarity are used to maintain a fixed brush drop and the stator frame is usually hydrogen-annealed to reduce to a minimum the effect of residual magnetism.

Figure 16 (below). Rototrol consisting of regulating generator and driving motor

Typical of units providing automatic control of such functions as speed, load or sheet tension in many applications throughout the paper mill

Figure 19. D-c 2-motor adjustable speed winder drive with regenerative braking and automatic sheet tension control

Produces high quality rolls at speeds in excess of 3,000 feet per minute in the finishing room of this mill

Figure 20. 150-horsepower d-c adjustable-speed supercalender drive with Rototrol threading speed regulator

The drive permits maintaining high productive efficiency due to high speed operation with controlled rates of acceleration and deceleration and stabilized threading speed

In pulp and paper mills Rototrols have been applied on paper forming machines to accurately maintain both the operating speed and relative speeds of individual sections of the machine. On supercalender drives Rototrols serve to maintain uniform threading speed and to synchronize the operations of the unwind and wind-up stands with the super-calender. In connection with both reels and unwind stands the Rototrol serves to maintain constant sheet tension as the roll varies in diameter between a full and empty roll. With the primary-couch roll drive as applied on many modern Fourdrinier machines it serves to maintain a motor driving effort consistent with the vacuum maintained in the roll. Applied to wet-end auxiliaries and other helper drives, the Rototrol maintains uniform operating conditions over the wide range of operating speeds. Due to the simplicity of its design the Rototrol presents no more of a problem to the mill operating personnel than a standard exciter unit. However, it provides an accurate and dependable means of automatic control.

Hydraulic Barking

The recent introduction of hydraulic barking in many mills, particularly those located on the west coast, has necessitated the development of a suitable motor drive. With hydraulic barking the bark is ripped from the log by high pressure and velocity jets of water directed tangentally against the surface of the log. Logs as large as 60 inches in diameter and 30 feet long can be handled in a single operation. This method of operation permits a saving in raw material as well as man power, and produces a clean well-barked log for the chipper. In normal operation it is necessary to move either the jets or the log from end to end and at the same time to index or rotate the log in order to completely remove the bark from the entire surface. Motor drives for the hydraulic barkers include power equipment for the nozzle carriages and the log manipulators as well as magnetic control providing complete control for a single operator from a pulpit type control station. To secure a high rate of production with logs of various diameters adjustable speed operation is ordinarily required of both the nozzle carriage and the log manipulators and direct current adjustable voltage drives are specified. Heavy production schedules require frequent reversals and the equipment is selected for this duty.

Full Log Chippers

To take full advantage of hydraulic barking of the large size log, chippers have been developed capable of handling 30-foot logs up to 42 inches in diameter. Such chippers are capable of chipping one of the large logs in less than 30 seconds. Synchronous motors in ratings from 1,000 to 2,000 horsepower have been developed for direct coupling to these chippers. These motors have high pull-out torques required to meet the peak load torques when chipping a full size log. These motors are selected of adequate thermal capacity to meet the normal production rate. They have extremely heavy mechanical construction to withstand the severe vibration resulting from the reaction of the chipper knives passing through the logs, and the damper windings are of special construction to permit acceleration of the high WR^2 of the chipper disk.

Supercalenders

Wide high-speed supercalenders equipped throughout with antifriction bearings for absorbing both radial and thrust loads have replaced older designs in the finishing room of the modern paper mill. These stacks are capable of handling sheets 160 inches in width at speeds in excess of 2,500 feet per minute. The modern supercalender drive provides an adjustable speed main stack drive with both synchronized wind and unwind stands. Such a drive includes a main d-c adjustable speed motor with suitable gearing for connecting to the lower roll of the main stack, a motor generator set for supplying power for the drive, and adjustable speed d-c units for connecting to both the unwind and wind-up stands. These drives also include full automatic control with a centralized control station and metering equipment indicating such operating conditions as speed, and sheet tension between the calender and both the unwind and the wind-up stand. These modern drives provide such operating features as stabilized threading speed, automatic current limit acceleration and deceleration between threading speed and pre-set operating speed, automatic control of sheet tension between calender and unwind and wind-up stands, adjustable speed operation over a wide operating speed range, inertia compensation preventing the loss of tension in the sheet when making speed adjustments, stalled tension, pay-out on unwinding stand, and slack take-up on the wind-up. These various operating features are required to obtain efficient operation of these modern high-speed supercalenders.

Finishing Room Equipment

In the finishing room the adjustable voltage d-c motor drive is suitable for many applications such as winders, past-

ers, corrugators, and waxing machines. Such a drive includes a motor generator set with direct connected exciter, one or more d-c motors for driving the process equipment either as a unit or in individual sections, and complete control for both a-c and d-c equipment. The power set serves to convert the mill power from alternating to direct current for use on the drives. The d-c motors may be operated over the required speed range by armature voltage control, by motor shunt field control, or by a combination of armature voltage and motor shunt field control. Speed adjustments are made by means of rheostats in either the generator or motor-field circuits. These rheostats may be either hand or motor operated. With motor operated rheostats the features of pre-set speed control as well as controlled rates of acceleration and deceleration may be obtained.

In conclusion attention should be called again to the important contributions electrical developments have made in the efficient operation of the mills of the pulp and paper industry. The economic generation and distribution of electric power together with its effective use has resulted in a high quality low-cost product which is required to meet the demands of an ever expanding market. Electric equipment properly selected, installed, and maintained assures many years of efficient operation in the many mills throughout the country.

Discussion

G. W. Knapp (General Electric Company, Schenectady, N. Y.): The comprehensive outline of electrical applications in the pulp and paper industry contained in this paper emphasizes the broad progressiveness of that industry.

Generation and Distribution

In the fields of generation and distribution, the industry is putting into practice forward-looking thinking. High pressures and temperatures are being used on turbines. (For example, 1,200 pounds per square inch and 950 degrees Fahrenheit total temperature on a recent 10,000-kw unit). Voltage levels are being raised for economy, present and future. System grounding is being used in many cases for protection to equipment and faster relaying.

In the application of transformers, many paper mill engineers feel that the dry-type should not be used in those locations where chemical fumes are present as in bleach plants, or where lint is prevalent as around tissue machines, unless ventilated, transformer rooms are provided.

Utilization Equipment

In utilization equipment, Baker's remarks are particularly timely. Electronics and rotating amplifiers (Rototrol. amplidyne, and so forth) have been used in the industry for more than ten years, and today they are given ready acceptance. One manufacturer has installed or has on order almost 400 electronic-amplidyne speed regulating equipments for both sectional and single motor drives. Approximately 200 additional amplidyne controls are being used for winders, super calenders, and wet end helper drives.

Recently, an experienced super calender engineer described a drive which is similar to that discussed by Baker, but with amplidyne control, as the finest he has ever seen

Certainly with such equipment available, and its progressive attitude, the paper industry on this continent can face the future with confidence.

Trends in Electronic Engineering

DONALD G. FINK
MEMBER AIEE

THE FIELD of electronic engineering has emerged in the postwar world as the most active branch of electrical science. Based fundamentally on the conduction of electricity in gases or in vacuum, electronics has come to include many branches of technology formerly classed as separate entities. As an introduction to this review of recent progress in electronic engineering, therefore, it is well to outline the field.

Electronic engineering divides, on technological as well as economic grounds, into three well-defined areas of activity:

1. Entertainment and education.
2. Communications.
3. Industrial applications.

The first classification includes broadcasting by amplitude modulation or frequency modulation, and comprises services for sound (sound broadcasting, motion pictures, phonograph recording, and public address) as well as visual transmissions (facsimile and television).

The second classification, closely related to the first, is concerned with the transmission of information other than for public consumption and includes the fields of telegraphy and telephony, between fixed or mobile stations, by wire or radio.

The third classification, the industrial applications of electronics, includes all parts of the field not related to broadcasting or communications. This field may be defined as the application of electronics in which the essential aspect is the control, guidance, or supervision of a process, or the manipulation or measurement of physical and mathematical quantities to perform an industrial process or commercial service.

Since industrial electronics is by far the most diverse aspect of electronic engineering, it requires a further breakdown. The first division is the guidance of commercial transportation, that is, the use of radio and electronic aids to navigation, traffic control, landing and docking, anticollision, and other safety services. This field has been classified loosely as an aspect of communications technology, as the techniques used in the two fields are similar. But in line with the definitions given above, radar, loran, and other navigational systems are clearly industrial applications.

The second division is the production and control of heat, such as control of resistance welding and the production of heat in conductors or dielectrics by immersion in high-frequency fields.

The third division includes the supervision of processes and protection against hazards. Intrusions alarms and monitors, and protection of operators against hazards presented by machinery are included.

The fourth division comprises continuous process controls. Such continuous processes as printing, wrapping, weaving, plating, rolling, perforating, finishing, sorting, and grading may be controlled or monitored by electronic devices sensitive to some physical quantity, such as weight, thickness, temperature, humidity, angle, position, balance, pressure, color, reflectance, or resistance.

The fifth application involves the manipulation of mathematical quantities, not for control purposes, but for computation. This group includes the many new forms of electronic computers of the digital and analogue types.

The sixth and final division is the large field of electronic measurements, not related to control. Many physical measurements, particularly those involving the perception of minute amounts of radiant or corpuscular energy, cannot be carried out except by photographic or electronic means. The electronic techniques have a considerable advantage over the photographic ones in respect to convenience.

With this brief outline of the field before us, we can proceed to a detailed examination of recent progress in each of the divisions just described.

Trends in Broadcasting

The field of broadcasting commands first attention because it represents by far the largest division of the field from the standpoint of economic investment and employment of technical personnel. Largely as a result of the universal presence of radio receivers in American homes there are, in North America, more electron tubes than there are people.

Considering first conventional sound broadcasting by amplitude modulation, it must be reported that few outstanding technical improvements have occurred in recent years. The principal recent trend in the United States has been along social and economic lines, namely, the very great increase in the number of stations occupying the already overcongested broadcast channels. In December 1945, there were 1,056 amplitude modulation broadcast stations in the United States and its possessions. Two years later, there were 1,961 such stations, an increase of nearly 1,000 stations in 24 months.

These new stations were authorized by the Federal Communications Commission (FCC) following a decision of the United States Supreme Court which, in effect, required the commission to issue licenses without considering the economic status of existing stations. As a result, interference among stations, particularly during nighttime hours, has increased, and this has focussed attention on directional antennas. Many stations have erected 2- and 3-element arrays to reduce the signal strength in direction of

Paper 48-128, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 9, 1948; made available for printing March 15, 1948.

DONALD G. FINK is editor in chief of Electronics, McGraw-Hill Publishing Company, Incorporated, New York, N. Y.

other stations occupying the same channel. Otherwise there is little change in the service to note. Network telephone-line connections continue, for the most part, to limit audio fidelity at 5,000 cycles per second. Similarly little change has occurred in the design of broadcast receivers, except that higher quality components and better audio systems are used in expensive models, largely because these receivers have facilities for frequency modulation.

In contrast, the progress of frequency modulation broadcasting in the United States during recent years has been marked. Frequency modulation station assignments are made in the band from 88 to 108 megacycles, with a few assignments still active on the older band, 44 to 50 megacycles. Stations in the latter region, notably station *W2XMN* in Alpine, N. J., operated by the inventor of wideband frequency modulation, Doctor E. H. Armstrong, have served as key stations in radio-relay frequency modulation networks which permit high-quality network connections without telephone lines. Telephone lines having an 8,000 cycles per second upper cutoff have also been used in frequency modulation networks, and early this year plans were underway for the use of lines with a 15,000 cycles per second cutoff.

At the end of 1947 there were 376 frequency modulation stations regularly on the air, and construction permits had been issued for 629 additional stations. By the end of 1948 it was predicted that there would be nearly 1,000 frequency modulation stations operating, or about the same as the number of amplitude modulation stations operating in 1945.

Approximately one million frequency modulation receivers were produced in 1947, which represented about one out of every 17 sets manufactured during that year. This represented a sixfold increase in production over the previous year. Frequency modulation receivers continue to be expensive, few table models selling at under 50 dollars. One step in the direction of cheaper frequency modulation sets is a new one-tube frequency modulation circuit combining the functions of superregeneration and the superheterodyne. While the performance of this simple circuit leaves much to be desired, it permits a combined amplitude modulation–frequency modulation table model set to be marketed for $30.

More rapid popularization of the frequency modulation service has been prevented by the action of Caesar Petrillo, head of the American Federation of Musicians, who refused to allow programs broadcast of the standard amplitude modulation stations to be broadcast simultaneously over frequency modulation stations without payment of double fees to the musicians. Consequently programs on frequency modulation stations consisted almost exclusively of phonograph records, and the listening audience was small. The Petrillo edict was withdrawn on February 1, 1948, and a steady increase in the frequency modulation audience since has occurred.

The power levels of frequency modulation stations, in the 88-to-108 megacycle band, range from 250 watts to 10 kw. Several 50-kw transmitters are in operation in the lower band, 44-50 megacycles. High-gain antennas, which compress the signal in the horizontal direction, are usual, producing an increase in effective radiated power of from two to six times. The effective range of a high-power transmitter with a high gain antenna is nearly 100 miles, if the receiver was located favorably although reception at ten miles may be unsatisfactory if large obstructions intervene.

Perhaps the most rapid progress of all, in the field of broadcasting, is that made by television. Permission to operate television stations commercially first was granted by the FCC in July 1941, but construction of new stations was halted immediately by the war. At the war's end, seven stations were in operation. At the end of 1947, 16 stations were on the air in 11 cities. Construction permits for 56 additional stations in 32 additional cities had been granted, and applications for 84 stations were pending before the FCC. In 1946, some 6,500 television receivers were manufactured; in 1947 this production had risen to 178,000. One large manufacturer reported that nearly half of the income derived from manufacturing radio receivers was accounted for by television sets.

The first television network took form along the Atlantic seaboard in 1947, connecting ten stations in Washington, Baltimore, Philadelphia, New York, and Schenectady. The coaxial cable, with a band width of 2.7 megacycles serves from Washington to New York. Microwave radio relays, operating at frequencies in the thousands of megacycles, connect New York, Philadelphia, and Boston. During a demonstration of the microwave relay system between New York and Boston (220 miles long), a television program was repeated back and forth over the system four times, or a distance equal to that from New York to Chicago, without visible degradation of the picture quality. Construction of a similar microwave relay between New York and Chicago is underway.

Television receivers range in price from $175 to $2,500, and produce pictures ranging in size from 4 by 6 inches to 15 by 20 inches, for home use. The larger size pictures are produced by a Schmidt projection system which enlarges the image from a small (4- or 5-inch) cathode-ray tube. Directive viewing screens for projection receivers enhance the image brightness by a factor of ten times, and permit satisfactory viewing in a sun-lit room. Of the 13 channels allocated by the FCC, no more than seven are assigned to any one locality. All commercial receivers have facilities for receiving any of the seven local stations, and many receivers provide tuning for all 13 channels. Picture brightness (in the highlights of the scene) of 50 foot-lamberts is achieved, with a contrast range as high as 100-to-1. The detail of the images varies from 100,000 to 150,000 picture elements per frame, depending on the excellence of the television camera in use and the effective bandwidths (three to four megacycles) employed by the receiver. The higher figure approximates closely the detail available from 16-millimeter motion pictures. The images are sent in a 525-line scanning pattern at a rate of 30 complete pictures per second.

Television for theaters is under active development. Images of six by eight feet were demonstrated at the International Telecommunications Conference in Atlantic City in the summer of 1947.

Among the most important of the recent technical developments in television is the image orthicon camera tube. This tube, which combines the properties of photoelectric emission, charge storage, and electron multiplication, is the most sensitive continuously registering light-sensitive device known to science. This camera will register an image under the illumination of a single tallow candle six feet from the subject. Such dim light will not actuate photographic film, when the same exposure (about 1/30th second) is used. In fact, the effective photographic speed of the image orthicon camera, for threshold values, is about Weston 2,000, compared with Weston 200 for the fastest photographic film.

The other form of visual broadcasting, facsimile, is ready for use, but has not been introduced to the public to any extent. Standards of transmission have been agreed upon by the industry and presented to the FCC, and experimental transmissions have occurred on a number of frequency modulation broadcast stations (being transmitted by multiplex

methods simultaneously with the f-m sound program) but facsimile equipment for the home is not as yet available and it appears that further co-ordinated effort by receiver manufacturers and broadcasters is required before the service becomes established. Facsimile service for communication purposes, particularly the transmission of news pictures and business documents, is well established at present.

Sound Reproduction

Widespread use of electronic techniques is made in entertainment and educational pursuits other than broadcasting. The sound aspect of motion pictures is a typical example. Since the advent of ultraviolet recording and the perfection of light-valve characteristics, little technical progress has been reported in this field. But in other types of sound recording, very rapid strides have been taken in recent years. In conventional disk recording the employment of better materials (particularly vinylite plastics) for pressings has resulted in a marked improvement of the tonal range, as high as 14,000 cycles in current British records, and a great reduction in the background noise inherent in the records.

An important and technically interesting improvement in the reproduction of disk records is the dynamic noise suppressor. In the form of suppressor developed by H. H. Scott, the tonal range of the reproduction is varied automatically and continuously, in response to changes in the volume of the recorded sound. Thus when the volume is low, the frequency range is restricted by an electronically controlled wave filter. This restriction removes noise, but does so only when the volume is low and the noise would be prominent if not removed. Since the tonal range to which the ear responds is naturally restricted at low volume levels, the tonal restriction is not perceived to any great degree. During loud passages of the music, the full tonal range is reproduced, as is required by the ear at high volumes, but the noise then is masked by the music and is not perceived. Such suppressors produce an amazing improvement in apparent signal-to-noise ratio on musical recordings, without audible degradation of the tone quality.

Another area of high activity in sound reproduction is the development of wire and tape recorders. The early forms of wire recorder had rather restricted tonal range, but reproduction faithful to 8000 cycles has been achieved on wire, and up to 13,000 cycles per second in tape recorders. The latter, following German practice, employ a finely-divided iron-powder emulsion deposited on a cellulose tape base.

Trends in Electronic Communication

Turning now to the field of communication by telegraphy, telephony, television, and facsimile, we encounter first an important addition to the theory of communication which has important practical implications in trunk-line telephony by radio relay. The new theory relates to the bandwidths required to transmit a given amount of information in a given amount of time. The classical statement of this relationship, the Hartley law, states that the minimum bandwidth, required in a communications channel to transmit information at a given rate, is equal to the spectrum occupied by the information itself. Thus, the band of frequencies occupied in commercial telephony extends from 250 to 2750 cycles per second. An ideal single-sideband system would require a frequency band at least 2,500 cycles per second wide to transmit this signal. If transmitted by double-sideband amplitude modulation, the band required is at least 5,000 cycles per second, and if wideband frequency modulation with a modulation index of 5 is used, the required bandwidth is at least 25,000 cycles per second.

The new theory takes into account the noise present in the transmission channel and states that the minimum bandwidth required is proportional to the quantity $\log (1+S/N)$ where S/N is the signal-to-noise power ratio in the transmission medium.

This law, derived independently by workers in the Bell Telephone Laboratories, Massachusetts Institute of Technology, and California Institute of Technology, has rather startling implications. The most important of these is that, if the signal-to-noise ratio in the transmission path may be made arbitrarily large (by employing an unlimited amount of power at the transmitter), the bandwidth required for full and accurate reproduction of the information may be made arbitrarily small. Thus, if resources are available to keep the transmitter power sufficiently high at each repeater point in a telephony, telegraphy, or television system, the bandwidth of the transmission system may be reduced below the extent occupied by the spectrum of the original intelligence. For example, a television signal, extending from 30 to 4,000,000 cycles per second as produced by the television camera, can be sent over a co-axial cable or radio relay system, having a bandwidth of only 2,000,000 cycles per second provided the signal-to-noise ratio is kept suitably high at each repeater point.

To achieve this important economy of spectrum utilization, a particular method of modulation must be used, the only practical form of which, now known, is "pulse-code modulation," described in the following. Although this system is probably not practical for broadcast use because of economic factors, it is quite possibly the optimum system of transmitting high quality telephone signals over restricted bandwidth in trunk service. Active investigation of the practical application of the new theory to telephone plant is now underway in several laboratories.

The second important trend in communication practice is employment of different modulation methods. Amplitude modulation continues to predominate in long-distance telephonic communications, and a modification of the amplitude modulation system in the form of single-sideband suppressed-carrier increasingly has been employed in long distance circuits, and has most recently been the subject of intensive activity among amateur radio telephone operators. Frequency modulation has been used widely in communications work, particularly the local services using frequencies from 30 megacycles upwards. A special form of frequency modulation system, frequency-shift keying for telegraphic circuits, has increasing vogue in long-distance work. Frequency modulation even has been proposed for international (transoceanic) broadcasting, but the wide band (about 200 kc) which is required for this service probably cannot be made available even for experimental work in the overcrowded bands between 5 and 25 megacycles.

For high-frequency carrier services (300 megacycles and higher) pulse methods of modulation actively are being developed and are employed to some extent in commercial practice. The two most prominent methods of pulse modulation are pulse time modulation and pulse-code modulation. In the first, a series of flat-topped steep-sided signals (pulses), of duration small compared with the interval between them, is set up as the basic transmission system. The intelligence to be transmitted is imposed on this sequence of pulses by varying the time of occurrence of the pulses in the sequence. This is, in effect, a phase modulation of the pulse, and the modulation may be recovered by passing the pulse sequence through a phase detector. This system has the

advantage that the transmitter and receiver need not be linear, as amplitude variations above threshold are of no consequence. Moreover, the pulses may be regenerated at repeaters by trigger action. The bandwidth required for pulse time modulation is generally more extensive than for amplitude modulation or frequency modulation but, at the high carrier frequencies for which the system is intended, sufficient ether space to accommodate the wide band is currently available.

The pulse-code modulation system, previously referred to, has important advantages over pulse-time modulation in that it permits a marked reduction in bandwidth if sufficient power is used. In the pulse-code system the amplitude coordinate of the signal wave is "quantized," that is, several discrete amplitude levels are set up as index points. The wave amplitude is then sampled at regular intervals of time, and the discrete amplitude level most nearly approached at each instant of sampling is translated into a code group, consisting of pulses of equal height, spaced in accordance with a binary code. The pulse code groups are transmitted and at the receiving point, each pulse group is retranslated into the corresponding amplitude level and the original signal wave thus is recreated in quantized form. If the number of amplitude steps set up is sufficiently great, the quantized nature of the reproduction is not noticeable. A binary code of 7 characters permits $2^7=128$ levels to be used and this structure is fine enough to permit reproduction of high quality speech and music; 32 levels suffice for commercial telephonic quality. The system employs regeneration of pulses at repeaters, a process made simple by the synchronous recurrence of the code pulses.

A third trend in communications practice is the great extension of radio facilities for communication in industries outside the common-carrier telephone and telegraph companies. As of December 1947, there were 877 communication stations licensed to public utilities, 972 to operators of busses, trucks, and taxis, and several score of stations to transit utility, petroleum pipe line, highway maintenance, and geophysical prospecting companies. The majority of these communication systems employ frequency modulation in the vicinity of 30-40 and 153-160 megacycles. Amplitude modulation also is used in these bands, but no more than two per cent of the stations employ this type of transmission.

A communication service still in the developmental stage, but promising much for the future, is the Citizens Radio Service. This service was established by the FCC in 1945, in the band between 460 and 470 mc (three-quarter meter wave length) for the use of any citizen, not possessing technical qualifications, for private or personal communication. Equipment for this service is not yet available to the public, but is under development. When available, any citizen may obtain authorization to use approved equipment for any private purpose, merely upon application, stating that he understands and will uphold the laws affecting radio communications.

A final development in the field of communications is the great extension of the ether spectrum now available. Prior to the war the spectrum allocated by the FCC extended upward to 300 megacycles, and services were not in use above 200 megacycles. Following the war, largely as a result of the wartime development of radar, the allocated spectrum was extended by the FCC to 30,000 megacycle (1 centimeter wave length). Communications system now in daily use occupy channels in the 2,000 and 4,000 megacycle range. Noteworthy in this category are the microwave relay systems, previously mentioned, for transmitting telephone and television signals from city to city in common carrier service.

Industrial Applications—Radio Navigation

We turn now to the industrial applications, and begin with one of the most important applications of electronic techniques to commerce, the guidance of aerial and marine transportation. Prior to the war this field was limited to the radio direction finder (direction-finder loop and Adcock aerial) and the radio-range course-marking beacon. But with the war came the active employment of several new radio aids to navigations, notably radar, hyperbolic navigation, and radar beacons. The principle of radar is by now well known. In the so-called nonco-operative type of radar, the radio wave sent is reflected by an otherwise passive object which differs from its surroundings. The direction and distance of the reflecting object are determined by directing a narrow beam toward it and timing the wave during its flight to and from the target. The resulting "echo" reflections may be displayed for visual inspection on a cathode-ray tube.

The most useful form of radar display takes the form of a map-like presentation, the center of the screen corresponding to the location of the radar, with reflecting objects shown at their proper relative distances and directions from the center. This "plan position indicator" now is widely employed as an aid to marine navigation, as it shows clearly the location and shape of coastlines and other landmarks useful in pilotage, and reveals the presence and courses of other ships. As such it serves not only as a navigation aid but as an anticollision device. Ships equipped with such radar equipment now may run with confidence, and even may negotiate narrow rivers, in fog or darkness. Current developments may produce a radar so rapid in its perception of echoes that it can "see" objects only a few tens of feet away and thus permit docking under conditions of poor visibility.

Although similar radar devices have proved of the utmost value in military aviation, they have not been applied to any great extent to commercial air navigation. Rather, radar has been applied to aviation from the ground, notably in the "ground-control approach" system (GCA). This system locates the position of an aircraft near an airport by a ground-based radar, and this information is relayed to the pilot by radio-telephone. In this manner the pilot may be guided into proper position for a landing and "talked" down to within a few feet of the ground. Air-borne radar is by no means a dead issue for commercial aviation. Recently a new lightweight radar (type *APS-42*) has been developed specifically for commercial aircraft.

A closely related system is the co-operative type of radar, in which specially-designed receiver-transmitters (radar transpondors) are set out as beacons. These receive the outgoing signal from a shipborne or airborne radar, and return a coded reply signal which is displayed, along with natural reflections, on the plan position indicator. In this manner the pilot of the radar-equipped vehicle can identify positively landmarks which otherwise might be unidentifiable or escape detection. One version of the radar beacon system is the distance-measuring equipment (DME) now being installed by the Civil Aeronautics Authority for commercial air line operation.

Still another specialized adaptation of the radar beacon is the shoran system, which times the reply signal from a beacon so precisely that the distance from aircraft to beacon can be measured to an accuracy of five yards, over distances of several hundred miles. Used for precision bombing during the war, shoran finds postwar application as an aerial survey instrument. Accurate charting of regions of the world by shoran has

revealed errors of many miles in charts at locations (notably the Caribbean) where local disturbances in the gravitational field have prevented accurate celestial measurements of position.

Another war-developed navigational aid of continuing peacetime use is the loran system. In this system stations on islands or coastlines transmit accurately synchronized pulses, broadcast over several hundred thousand square miles of the adjacent sea. The navigator of a loran-equipped ship or aircraft observes these pulses in pairs on a cathode-ray screen in such a way that he can determine the difference in the time of arrival of the two sets of pulses at his location. As the time difference between the pulses emitted by two stations is a constant along a hyperbolic locus projected on the earth's surface, measurement of this time difference suffices to locate the navigator on one of a family of such loci, which are printed on charts of the region. Similarly measurements on a second pair of pulses from two other stations (one of which may be common to the first pair) places the navigator on another locus, intersecting the first. The point of intersection, which represents the navigator's position, can be determined to an accuracy of a few miles at distances as great as 1,500 miles from the stations.

At the end of the war, nearly one third of the earth's surface was covered by loran hyperbolic coordinates, and a large portion of this service is still maintained by stations operated by the United States Coast Guard and agencies in other countries. Nearly 1,000 transoceanic flights now are completed each month by loran-equipped aircraft and scores of merchant vessels, in addition to all naval vessels and many military aircraft, use the system.

Many other navigational systems are under development, most of them aimed at the as-yet-unsolved problem of controlling dense airt raffic in the vicinity of airports. These combine radar, radar beacons, television, and radar altimeters (automatic height finders). The latter device is a radar which measures the distance of the aircraft above ground by timing the interval of reflection of a signal sent from the airplane after it strikes the ground and returns to the aircraft.

Electronic Production of Heat

Electronic heating by the immersion of substances in high frequency fields has grown in importance very substantially in recent years. In view of this increasing use, and in view of the severe interference to communication and broadcast services which may be caused by industrial heating equipment, the FCC in 1948 set up three frequency assignments for "scientific industrial and medical" equipment. These assignments consist of bands, centered on 13.56, 27.12, and 40.68 megacycles. All medical diathermy and industrial heating equipment which cannot be shielded adequately must employ a frequency in these bands.

The principal trend in this field is the use of higher frequencies and higher powers. Frequencies in the thousands of megacycles have been employed to preheat high-quality plastics material prior to molding, to defrost frozen foods, and to cook foods. Continuous-wave magnetrons are employed to generate several kilowatts of power at these ultrahigh frequencies, the energy being conducted through waveguides to a chamber containing the material to be heated. Frequencies in the 10-30 megacycle range have been employed widely to set glue, notably in the furniture and plywood industries. Drying of rayon cakes is also an important potential application.

Somewhat lower frequencies are used in metal hardening, brazing, and soldering operations. One of the largest units in metallics service is a 200-kw generator, operating in the hundreds of kilocycles, used to flow tin in the tin plate industry.

An allied technique, not involving the production of heat, is the preservation of foodstuffs by passage of cathode rays through the food. A new electron tube, the capacitron, operates at five million volts and produces an intense beam of cathode rays, limited in duration to a few microseconds. So intense are these rays that they emerge through a thin window at one end of the tube and may be passed directly through food or other perishable substances. The high intensity of the bombardment, coupled with its short duration, excites a preservative radiation within the foodstuff without producing sufficient heat to induce chemical changes. The effect of the bombardment, in the majority of foods thus far tested, is to kill bacteria and other micro-organisms, and to inhibit the activity of enzymes to such an extent that food will remain fresh for months without refrigeration, and in fact with no treatment whatever except cover to prevent loss of moisture. Meat and poultry, fats and oils, vegetables (except lettuce, which wilts under treatment), fruits, and perishable drugs have been treated successfully. The treatment may be applied to food in any form, dried, frozen, raw, partly or fully cooked, since no chemical change is produced by the passage of the cathode rays.

Trends in Process and Machinery Controls

Among the application of electronic controls to machinery and processes, is a notable trend toward the use of thyratron motor controls on small machine tools. Technically this device is not new, but its extensive penetration into the metal-working industries is of recent date. The motor control serves to give smooth control of motor speed and torque without loss of efficiency.

Noteworthy among recent continuous process controls is a register control which combines an electronic computer and a hydraulic mechanism for correcting the register between successive imprintings of colored ink on paper or metal. The over-all performance of this register control is outstanding: register is held with an error on 1/1,000 inch while the printed material is passing through the press at a speed of 1,000 feet per minute. Register marks printed by the first color are viewed by a photo tube which develops an electric pulse of current as each register mark passes. These pulses are shaped and passed to a computer unit which determines the rate of passage of the marks and detects any difference in the rate relative to the printing speed of the succeeding color. Immediately that such an error is detected, it is amplified to the level of about 25 watts, and actuates a hydraulic valve which drives a differential connected to the printing rolls. The production of a pressman operating a press fitted with this register control is tripled. As the electronic components must operate, in certain applications, in an explosive atmosphere, all tubes and components are immersed completely in oil and sealed hermetically.

Another continuous process control of recent date is the X-ray thickness gauge, used to monitor the rolling of hot-rolled steel sheets. Since the sheet is very hot when rolled, simple contact gauges have short life and are inaccurate at best. An X-ray gauge, which does not touch the sheet, operates as follows: an X-ray tube on one side of the sheet irradicates it with rays of intensity just sufficient to penetrate the sheet and cause a fluorescent screen on the other side to emit light. This light is viewed by a photoelectric tube in a balanced circuit; the output of the photoelectric tube is thus sensitive to minute changes in the fluorescent light, such as are caused by very slight changes in the thickness of the sheet. The photoelectric tube current indicates to the mill operator the extent of the thickness variations, and even may be used to maintain

the thickness automatically within desired limits.

An application of electronics in the aviation industry, capable of similar savings in costs of operation, is the electronic aircraft engine analyzer. This is a cathode-ray oscilloscope connected to the ignition harness of an aircraft engine in such a way that the voltage across each of the spark plugs individually is represented as a function of time. The resulting wave form is an accurate index of the excellence of the ignition process and in particular will indicate impending ignition failure before it occurs. When so detected, a faulty spark plug may be identified and replaced in a very short time, often while the aircraft is making a scheduled stop. Without the engine analyzer faulty ignition cannot be detected in advance, and the time lost in finding a faulty plug may cost several thousand dollars in revenue lost while the aircraft is out of service.

Among the telemetering devices, one of the most interesting is the application of television to the monitoring of water level in high pressure boilers. To safeguard such boilers, it is customary to install complicated systems of mirrors, and safety laws require an operator to watch the water-level tubes at all times. Extensive research has proved that it is difficult, if not impossible, to replace the mirror system with a less cumbersome telemetering system, because the telemetering system might give a false indication and thus place lives and property in grave jeopardy. A satisfactory alternative was found in television, a television camera to view each of several water gauges and a group of viewing screens so arranged that a single observer can monitor several units simultaneously. Television proved satisfactory because it cannot give a wrong indication; it either shows the gauge level properly or it shows nothing at all. In event of failure of the television system, of course, rapid recourse must be taken to the mirror system, which is installed as an auxiliary to the television system.

Electronic Computers

As a concluding classification, we shall consider devices which are perhaps the most significant of all electronic devices now in process of development, the electronic computers. By making possible rapid computations from huge masses of data, problems formerly impossible of solution now may be solved. One possible result is accurate long-range weather forecasting. Another is the computation of all sorts of mathematical tables, from Bessel functions to nautical almanacs, in weeks rather than years.

Two types of electronic computer have merged in recent years, the analogue computer and the digital computer. The analogue type is a combination of electronic circuits which is in effect on electronic model of the device or process whose operation is to be computed. Circuits capable of adding, subtracting, multiplying, dividing, differentiating, and integrating are known and may be so combined as to perform a sequence of operations producing directly a variation of current or voltage which represents the desired solution. These computers have the advantage of comparative simplicity, but are limited in the accuracy with which they can compute.

The digital computer is, in essence, a counting device capable of extremely rapid action. As all mathematical operations may be reduced to a series notation which is, in effect, a counting process, the digital computer is of extremely wide application and its accuracy may be extended to any desired limit by multiplying the number of counting units. The Eniac computer, one of the first of the digital type, employs 18,000 tubes. A more recent embodiment of this principle, the International Business Machines computer, employs 12,500 tubes and operates with almost unbelievable speed and range.

The basic mathematical data are introduced to this machine by punched cards, and similar cards are employed to set up the sequence of mathematical operations. Numbers of 19 digits may be accommodated, and operations may occur at the rate of 24,000 digits per minute. Intermediate totals in a computation may be stored electronically, in electromechanical relays or punched tape, the total storage capacity being 400,000 digits. Using this computer, the position of the moon, an important element of nautical almanacs, may be predicted for any time for hundreds of years in the future, in seven minutes of computing time. The mathematical process involves summing a series of 1,600 terms, that is, performing 9000 multiplications, 10,000 additions and subtractions, and taking 1,800 values from trigonometric tables.

With such comprehensive mechanisms available, it is certain that vastly complicated processes of nature, particularly those now opening up in nuclear science, soon will be capable of analysis. With the understanding such analysis will provide, we may look forward confidently to a broader and more comprehensive technology.

Power Development in Mexico

ALEJANDRO PAEZ URQUIDI
ASSOCIATE AIEE

ALFONSO FERNANDEZ DEL BUSTO
MEMBER AIEE

GERMAN GARCIA LOZANO
NONMEMBER AIEE

AT the Southwest district meeting held at San Antonio, Texas, in April 1946, the Mexico Section of the AIEE presented a paper entitled, "Mexico's Electrification Program," in which an analysis was made of the estimated requirements to supply the increasing demand of electrical energy up to the end of 1949. Although only two years have passed since that meeting, it may be of interest to review briefly the results achieved in a problem so vitally important for the industrialization of the country.

The previous paper explained the urgency of increasing the installed generating capacity by 53 per cent in the following four-year period and that, in order to accomplish this, new generating plants with a total capacity of 400,000 kw were required. The statistical information gave our installed capacity for 1945 as 756,000 kw, and therefore, in accordance with that paper, a total capacity of 1,156,000 kw should be available by the end of 1950.

The results obtained during the last two years, that is up to the end of 1947, are as shown in Table I. It would appear that the forecast made for 1947 was on the high side. However, it should be taken into consideration that the generation in 1947 was below what should have been generated due to delays in the delivery of power plant equipment that had been ordered in the United States, and which were caused by the strikes that handicapped the majority of the industries in that country. This situation was further aggravated by an extraordinary shortage of water during the dry season at the beginning of 1947 that affected the generation in three of the most important hydroelectric systems supplying over 80 per cent of the total production in the country. As a consequence, the generation in these systems had to be reduced and restrictive measures on the use of electric energy were imposed in several of the most important zones of the country. In some places, the use of energy was restricted to 50 per cent of the normal consumption.

Table I

	Kilowatt-hours
Energy generated during 1945	3,068,000,000
Energy to be generated during 1946 as per forecast made early that year	3,460,000,000
Actual generation during 1946	3,317,000,000
Energy to be generated during 1947 as per forecast made early in 1946	3,840,000,000
Actual generation during 1947	3,598,000,000

The energy (in kilowatt-hours) that could not be generated for the foregoing reasons is estimated as follows:

The Mexican Light and Power Company, Limited, and subsidiaries	70,000,000
Nueva Compañia Electrica Chapala, S.A., and subsidiaries	33 000,000
Guanajuato Interconnected System	28,000,000
Total	131,000,000

Had it not been for these reasons the actual generation in 1947 would have been only 2.9 per cent below the forecast made in 1946.

Figure 1 gives the generation up to 1947 inclusive and the probable generation for the period 1948–1950.

If the forecast as regards generation was on the high side for 1947, that made on the installed capacity was surpassed because at the end of last year the installed capacity reached 963,000 kw, showing an increment of 207,000 kw in two years as compared with the increment of 400,000 kw considered as necessary in 1946 for the following period of four years. It should be borne in mind that a large portion of the additional capacity came into service in December 1947, this being the reason why this additional capacity could not give a proportional increase in the generation.

If the generation, in addition to the imported energy, and the installed capacity in 1945 and 1947 are compared, respectively, with the population recently estimated for these same years, the indexes shown in Table II are obtained.

In order to meet the increasing demand, consequent to the industrialization program of the country, new power plants and additions to existing ones are in process of construction and it is expected that 359,900 kw in additional generating capacity will be available in the next three years.

The plants now in course of construction are seen in Table III. Other projects for new plants and additions to existing ones, for a total capacity of 700,000 kw, are being studied and it is expected that the majority of them will be in service by the end of 1952.

As an interesting instance, among the plants in process of construction may be mentioned a 30,900 kw diesel-electric power plant being erected in the Federal District by the Cía Mexicana Meridional de Fuerza, S.A. The engines of the six units to be installed will be the largest ones built up to the present time in the

Paper 48-158, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted March 19, 1948; made available for printing May 12, 1948.

ALEJANDRO PAEZ URQUIDI is executive director, Comision Federal de Electricidad, Mexico, D. F., Mexico; ALFONSO FERNANDEZ DEL BUSTO is with the Mexican Light and Power Company, Limited, Mexico, D. F., Mexico; and GERMAN GARCIA LOZANO is chief of rate department, Nueva Compañia Electrica Chapala, S.A., Mexico, D. F., Mexico.

The Institute is indebted to the Mexico City Section for the translation of this paper from Spanish into English.

Table II

	1945	1947
Population (estimated)	22,226,000	23,219,000
Installed capacity, kilowatts	756,000	963,000
Generation, kilowatt-hours	3,068,000,000	3,598,000,00
Imported energy, kilowatt-hours	59,000,000	89,000,000
Total energy, kilowatt-hours	3,127,000,000	3,687,000,000
Installed capacity per capita, watts	34	41.5
Kilowatt-hours per year per capita	140	158

United States. Each engine will have 12 cylinders, 29 inch bore, and 40 inch stroke, with a brake horsepower rating of 8,650 horsepower at sea level and 7,325 horsepower at 2,257 meters altitude. It is expected that this plant will start operating by September 1948.

As was pointed out in the paper presented at the meeting in San Antonio, Texas, not more than 27.5 per cent of the total population of the country is concentrated in cities of 5,000 or more inhabitants and not more than 20 per cent of the population benefits from electric service, showing that the majority of the population is scattered in rural zones without electricity.

These sparsely populated rural centers cannot offer an incentive for electrification to the privately-owned utilities because, in the majority of cases, they cannot expect a reasonable return on their investments, mainly during the first stages of the development. This has really created a vicious circle. The meagerness of the market does not justify, economically, the installation of a power plant and the lack of such a plant prevents the expansion of the zone. In order to break this circle, and considering the problem from a social viewpoint rather than its lucrative end, the Federal Commission of Electricity has undertaken a vast program of rural electrification and expects that by carrying it out the economical situation of these zones and the standard of living of the population will be greatly improved.

To illustrate how this program has been planned, a brief description of the work being done in the State of Veracruz may be of interest.

As a first step, a field survey was carried out of all villages with more than

Figure 1. Total power generation and installed capacity

1,500 inhabitants lacking electric service or with such a deficient one that it could not be considered as a "public service." A topographical map was made of each village, classifying every house by its category and indicating for each the probable load. A similar census was taken of all the industries operating with small plants and of those now using hand labor exclusively but which could be electrified. In this way, a fair estimation of the requirements of each village and of its surrounding agricultural district was made.

After spotting these villages on a map of the state, those relatively close to each other were grouped together to form small isolated systems, each to be provided with a Diesel power plant and the necessary rural type distribution lines.

The villages were grouped in such a way that later on, depending on the power facilities and the demand, some of the groups can be interconnected to make larger systems until a stage is reached when the erection of transmission lines joining together all these groups becomes justifiable from an economical standpoint.

Every time that two or more of the initial small groups are interconnected a larger plant will be provided to feed the larger system thereby reducing gradually the number of small plants.

A standard type of power plant has been selected for the initial steps of the

Table III. Plants Now Under Construction

Totals	181,900	178,000
Grand Total	359,900 kw	

program, consisting of diesel units of from 100 to 300 kw. In order to provide adequate maintenance, without affecting the continuity of service, each plant will have a complete spare generating unit.

When selecting the equipment, special attention was given towards standardization, not only for different units of the same plant but also for the various plants that may be installed all over the country.

This will permit reducing to a minimum the investment in spare parts, giving at the same time more flexibility to the use of such parts and a more ready and reliable maintenance.

Another advantage of this standardization is that the operating and maintenance personnel will have to get acquainted with only one type of equipment and will gradually acquire a higher degree of specialization.

In the State of Veracruz, selected as an illustration of this program, 76 villages with a total population of 166,000 inhabitants have been grouped into 36 small systems, each to be provided with a power plant of 200 to 900 kw; the total plant capacity to be installed is 14,400 kw.

This brief outline shows the effort made by the Mexican Government and the cooperation given by the privately-owned public utilities to carry through the program of electrification so important for the welfare of the country.

Primary Detectors for Measurements

E. E. LYNCH
MEMBER AIEE

A. J. CORSON
MEMBER AIEE

The basic elements of any measurement system may be classified into three functional groups known as primary detectors, intermediate means, and end devices. By classifying the primary detectors for both electrical and nonelectrical quantities, convenient selection of a suitable detector may be made when the quantity to be measured together with the range over which it will vary is known.

IN VIEW of the growing importance of measurements to technical progress, it is surprising that only limited attention has been given to a complete functional analysis and classification of the whole measurement field. One excellent step in that direction has been made. In essence, this consists of classifying the basic elements of any measurement system into three functional groups known as the primary detectors, the intermediate means, and the end devices.[1-3] These groups are shown schematically in Figure 1 and each group may be composed of one or more sets of measurement components called basic elements. Each basic element may operate with others in series or in parallel or in any complex manner.

This article is written as the result of a more detailed study of the functional groups just mentioned and will lead to a more complete realization of the advantages of the over-all analysis. A method of treating and analyzing one particular group of any measurement sequence is presented in a novel and useful manner. The first group, the primary detectors, is discussed in this article. This investigation results in a method of classification which is suitable for choosing the primary detector best adapted for measurement of a particular quantity. It serves as a guide toward effectual further study of obtainable accuracies and it indicates other detectors which might be used as substitutes. It also presents a standardized method of analyzing any primary detector, a method which will result in a practical understanding of both the steady state and transient operation of this part of the measuring system.

The primary detector in a measurement system has been defined as the first basic element or group of elements that responds quantitatively to the quantity measured and performs the initial measurement operation. For example, in a simple measurement of radio-frequency current, it consists of a thermocouple converter as shown in Figure 2. In a more complex system, the detector may be a separate device such as the a-c generator of a railway tachometer, as illustrated in Figure 3. Moreover, a primary detector may be a relatively simple unit such as a thermocouple, or more complex as in the case of a watt-hour meter mechanism.

CLASSIFICATION OF PRIMARY DETECTORS

Applications of primary detectors naturally fall into two classifications: (*a*) those used in measuring electrical quantities, and (*b*) those used in measuring nonelectrical quantities. Typical results of such classifications are shown in Tables I and II.

These tables are arranged in a form convenient for the selection of a suitable detector when the quantity to be measured together with the range over which it will vary is known, since these are the first two columns in the tabulation. In using the tables it should be understood that the "range of measurement" applies to the order of magnitude with readily available detectors and may be extended considerably for special applications using detectors specifically designed for such use. The range in many cases is shown from zero to a specified maximum and this indicates that instruments with scales indicating down to zero are available. The minimum limit of measurability in such cases depends on the sensitivity of the instrument and the allowable accuracy for the application.

The third column of Tables I and II lists a common name for the detector and this is followed by the basic elements used in the construction of the primary detector in the fourth column.

The action of the detector is described by the next three columns headed the input, the physical effect, and the output, respectively. The last column names one particular instrument in which the application of the primary detector is adequately illustrated. In most cases several other available instruments might have been used equally well to show the application of the primary detector.

A careful study of the tables together with a visualization of possible intermediate means and end devices will demonstrate the value and benefits which can be derived from such information. For instance, when it is known that accuracy requirements will dictate a servomechanical system, a primary detector suitable to this application can be selected. It is realized that the tables do not cover all the primary detectors used in measurements. It is believed that they include most of the detectors widely used in common applications. Undoubtedly additions to the tables in the future will keep them up to date with respect to new detectors which may be invented and also add to their usefulness.

Full text of paper 48-104, recommended by the AIEE instruments and measurement committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1-3, 1948. Manuscript submitted November 13, 1947; made available for printing February 26, 1948; scheduled for publication in AIEE *TRANSACTIONS*, volume 67, 1948.

E. E. Lynch and A. J. Corson are engineers at the West Lynn (Mass.) works of the General Electric Company.

Among the authors' associates who have contributed to this study of primary detectors are I. F. Kinnard (F'43) and H. C. Dickinson (A'37). F. E. Arnold was particularly helpful in the collection of data for Tables II and III.

Figure 1. General functional classification for measurement systems

Arrows show general direction towards which outputs and inputs are directed. The flow need not be as direct as indicated. Feed-back and parallel paths frequently are used in measurement systems of the servomechanism type

SELECTION OF PRIMARY DETECTORS

It has been pointed out that the headings of the first two columns of Tables I and II adapt them to use in selecting a primary detector for a specific application. For this reason the primary detectors used for the measurement of a particular quantity are grouped together.

In preparing Tables I and II it was necessary to determine exactly what portion of each measurement system should be used as the primary detector. Based on its definition Tables I and II are arranged to give a convenient and useful classification of numerous primary detectors.

An example such as the permanent-magnet moving-coil mechanism (Table I) illustrates a criterion for determining which of the basic elements of a measurement sequence constitutes the primary detector. This mechanism basically detects current. The first complete measurement operation consists of the effects up to and including the production of torque. Thus, in a simple d-c ammeter the primary detector consists of the moving coil and the permanent magnet which together produce the torque. Sometimes this torque terminates in angular displacement of a spring controlled moving system. In other applications the countertorque is electrodynamic with no definite torque–deflection characteristic. For this reason the functional output of the permanent-magnet moving-coil mechanism is torque rather than deflection.

This same mechanism is also useful in measuring direct voltage. A resistance is used in series to obtain a suitable current magnitude. The operation in going from voltage to current by means of the impedance of the resistor is not considered a complete operation. This is a matter of convenience. The nature of voltage and current is so closely allied that the resistor together with the permanent-magnet moving-coil mechanism is classified as the primary detector with torque as the output. Similar combinations of resistance or impedance networks are used with electrodynamic and other detectors.

There are other examples where the permanent-magnet moving-coil mechanism is used in a measurement sequence but not as the primary detector. In the light meter (Figure 4), the nature of the cell output is so different from the input that the cell automatically falls into the classification of the primary detector.

Figure 2. Radio-frequency ammeter

THE INPUT

The primary detector as shown in Figure 1 has a functional input and a functional output. These quantities are not to be confused with the power or energy input and output which are the cause and result of the primary detector's operation. For example, in Figure 3 the railway tachometer primary detector is an a-c generator with a power input and output expressable in horsepower or kilowatts. However, the functional input is speed and the functional output is voltage.

The measured quantity is often, but not always, the input to the primary detector. Cases where it is not convenient to consider the measured quantity as the input are as follows:

(*a*). When the measured quantity is represented by several component quantities and these components are used as inputs. The thermal watt demand meter, Figure 5, includes a primary detector for a-c power where alternating potential and current, phased according to their power factors, are the inputs.

(*b*). When a factor of the measured quantity is introduced elsewhere in the measurement sequence such as shown in the single-phase var-hour meter, Figure 6. Var-hours is the measured quantity, and

Table I. Typical Primary Detectors for Measurement of Electrical and Magnetic Quantities

	Quantity Measured	Range of Use	Name	Basic Elements	Input	Physical Effect Output = Kf (Input)	Output	Typical Application
1	Direct current	From 0 to 1 amp	D'Arsonval mechanism	Permanent magnet and moving coil	Direct current	The field of the magnet produces a torque on the current carrying conductors of the moving coil.	Torque	D-c ammeter
2	Direct current	From 0 to 10 amp	Moving magnet mechanism	Fixed coil moving permanent magnet	Direct current	The magnetic field of the fixed coil produces a torque on the moving magnet.	Torque	D-c ammeter
3	Direct potential	From 0 to 5,000 v	D'Arsonval mechanism	Permanent magnet, moving coil, and resistor	Direct potential	The potential, applied to a calibrated resistor, results in current $I=E/R$ which is measured as in (1).	Torque	D-c voltmeter
4	Direct potential	From 0 to 100 v	Moving magnet mechanism	Fixed coil, moving permanent magnet, and resistor	Direct potential	The potential, applied to a calibrated resistor, results in a current $I=E/R$, which is measured as in (2).	Torque	D-c voltmeter
5	Alternating or direct current	From 0 to 600 amp	Moving-iron mechanism	Fixed coil and ferromagnetic vane	Current	The magnetic field of the fixed coil induces magnetic poles in the moving vane causing attraction or repulsion.	Torque	A-c or d-c ammeter
6	Alternating or direct current	From 0 to 100 amp	Thermocouple	Resistor and thermocouple	Current	The current heats the resistor, the temperature rise of which produces electromotive force at the junction of 2 dissimilar metals.	Potential	Thermoammeter
7	Alternating or direct current	From 0 to 1.0 amp	Electrodynamic mechanism	Fixed coil and moving coil	Alternating or direct current	The magnetic fields of the fixed and moving coils interact to produce a torque.	Torque	A-c or d-c ammeter
8	Alternating or direct potential	From 0 to 750 v	Moving-iron mechanism	Fixed coil, moving iron, and resistor	Alternating or direct potential	The potential, applied to a calibrated noninductive resistor, results in a current $I=E/R$, which is measured as in (3).	Torque	A-c or d-c voltmeter
9	Alternating or direct potential	From 0 to 750 v	Electrodynamic mechanism	Fixed coil, moving coil, and resistor	Alternating or direct potential	The potential applied to a calibrated noninductive resistor, results in a current $I=E/R$ which is measured as in (7).	Torque	A-c or d-c voltmeter
10	Frequency	From 0 to 1000 c	Resonant circuit	Fixed inductors and fixed capacitors	Potential of variable frequency	The current-voltage relationship in the resonant circuit is a measure of the frequency.	Current or voltage	Frequency meter
11	A-c or d-c power	From 0 to 450 kw	Electrodynamic mechanism	Fixed coil, moving coil, and resistor	Current and potential	The magnetic fields of one fixed and one moving coil interact to produce a torque proportional to their instantaneous product.	Torque	Wattmeter
12	Power factor	From 0 to 1.00	Electrodynamic mechanism	Fixed coil, 2 moving coils, fixed resistor, and fixed inductor	Current and potential with variable power factor	The magnetic fields of one fixed and two moving coils interact to produce angular displacement when power factor is changed.	Angular displacement	Power factor meter
13	Energy (a-c)	From 0 to 10,000 kwh at rates up to 90 kw (600 v, 150 amp)	Watt-hour meter mechanism	Electromagnet, braking magnet, and eddy-current disk	Current and potential	The reaction of fluxes of the electromagnet with eddy currents induced in the disk by these fluxes produces a torque. This torque, when opposed by the braking torque of the permanent magnet, results in angular disk displacement proportional to energy.	Angular displacement	Watt-hour meter
14	Reactive energy (a-c)	From 0 to 10,000 rkva hr at rates up to 90 rkva (600 v, 150 amp)	Watt-hour meter mechanism and phase shifting transformer	Phase shifting transformer, electromagnet, braking magnet, and eddy-current disk	Current and phase-displaced potential	Same as (13)	Angular displacement	Reactive volt-ampere hour meters
15	Power demand	From 0 to 24 kw	Bimetallic actuator	Bimetallic actuators	Current	Input currents from voltage and current sources are combined in opposing bimetallic spirals to produce displacement as a function of power.	Angular displacement	Thermal watt demand meter
16	Energy (d-c)	From 0 to 10,000 kwhr at rates up to 9,000 kw (750 v, 12,000 amp)	D-c watt-hour meter mechanism	Fixed air-core coil, moving air-core coil, commutator eddy-current disk, and braking magnet	Current and potential	The magnetic fields of the fixed and moving coils interact to produce a torque. This torque when opposed by the braking torque of the magnet and disk, results in angular displacement proportional to energy.	Angular displacement	D-c watt-hour meter
17	Phase angle	From 0 to 360 deg	Phase angle meter mechanism	Electromagnetic stator, fixed coil, ferromagnetic vane, fixed resistors, and fixed capacitors	Two potentials	The interaction of magnetic fields due to two potentials causes displacement of the moving vane as a function of the phase angle.	Angular displacement	Phase angle meter (synchroscope)
18	Resistance	From 1 to 100 × 10^8 ohms	Permanent magnet moving coil mechanism	Permanent magnet, moving coil, and constant voltage source	Resistance	The constant potential applied to the resistance under measurement produces current flow $I=E/R$ which is measured as in (1).	Torque	Ohmmeter

Table I (Concluded). Typical Primary Detectors for Measurement of Electrical and Magnetic Quantities

	Quantity Measured	Range of Use	Name	Basic Elements	Input	Physical Effect Output = Kf (Input)	Output	Typical Application
19	Resistance	0.01×10^{-6} to 10×10^{6} ohms	Resistance bridge including galvanometer	Fixed resistors, variable resistors, voltage source, permanent magnet, and moving coil	Resistance	A resistance change in a balanced bridge network causes a galvanometer deflection, which results in adjustment of variable resistors to re-establish bridge balance.	Mechanical displacement	Resistance bridge
20	A-c flux	magnetic	Search coil	Search coil	A-c flux linkages	The flux linkages induce a potential in the coil. This potential is a function of the rate of change of flux.	Potential	Flux voltmeter
21	D-c flux	magnetic	Moving search coil	Search coil and means of motion	D-c flux linkages	The moving search coil is the source of a quantity of electricity proportional to the change in flux linkages.	Quantity of electricity	Ballistic fluxmeter
22	Magnetic strength	field	Moving magnet	Moving magnet	Field strength	The field exerts a torque on the magnet as a function of this field strength.	Torque	Magnetometer

time (hours) is introduced by the integrating function of the detector. The inputs are properly phased alternating potential and current and the output is the angular position of the disk.

THE OUTPUT

The functional output of the primary detector energizes or controls the operation of the end device. The output may be the input to an end device directly as shown in the radio-frequency ammeter, Figure 2, or it may be the input to an intermediate means as shown in the tachometer, Figure 3. The output of an ideal primary detector should bear an exact relation to the steady-state condition of the input. As an example, the output of a watt-hour meter mechanism (Figure 6) when measuring var-hours must be angular deflection. This is the first quantity that represents quantitative response to var-hours. The torque of the driving element is proportional to vars but not to var-hours. Torque, therefore, cannot be the output. The input–output relationship, Figure 7, must be repeatable within the required precision of measurement. This precision must be sustained in most cases over long periods of time.

If the measured quantity varies rapidly, the output inherently will contain additional transients. At times such action is desirable. A thermal watt demand meter, such as shown in Figure 5, utilizes the thermal capacity and heat insulation characteristics of the primary detector to obtain the desired transient or lagged response. In the radio-frequency ammeter, shown in Figure 2, the heat constants are so chosen that the output response is slow compared to radio-frequency cyclic changes of the input. Only the rms value of the current appears in the output. The lagging characteristics of the detector thus are utilized advantageously.

Transients also occur at times when they are undesirable. In such cases the magnitude or time constants of the transient must be negligible. If it is impossible or not feasible to accomplish this, the primary detector is unsuitable for measurement of rapidly varying quantities. Since electric networks (due to their impedance) and mechanisms (due

	Quantity Measured	Range of Use	Name	Basic Elements	Input	Physical Effect Output = Kf (Input)	Output	Typical Application
1	Temperature	From −200 C to 1,760 C	Thermocouple	Thermocouple	Temperature	An emf exists at the junction of dissimilar metals. A temperature difference at two junctions results in a potential difference.	Potential	Thermocouple thermometer
2	Temperature	From −240 C to 600 C	Resistance temperature detector	Temperature sensitive resistor	Temperature	Electrical resistance changes with temperature.	Resistance	Resistance thermometer
3	Temperature	From 800 C to 2,000 C	Disappearing filament	Incandescent filament lamp and d-c source	Temperature	Light emitted from a glowing body depends on temperature and its intensity can be matched visually against an adjustable standard such as the filament of an incandescent lamp.	Light intensity	Disappearing filament optical pyrometer
4	Temperature		Phototube	Photo sensitive cell	Temperature	Light emitted from a glowing body depends on temperature and can be used to actuate a photosensitive cell, the resistance of which, as a circuit element, is a function of temperature.	Effective resistance	Automatic optical pyrometer
5	Temperature	From 500 C to 2,000 C	Thermopile	Radiation thermocouple	Temperature	Radiant heat from a hot body alters the temperature of a thermojunction so that the thermocouple potential difference is a function of temperature.	Potential	Radiation pyrometer
6	Temperature	From −100 C to 400 C	Bimetallic actuator	Bimetallic actuator	Temperature	Two joined metal strips with different expansion coefficients will bend as temperature changes.	Mechanical displacement	Bimetal thermometer
7	Temperature	From −190 C to 500 C	Liquid-in-glass expansion bulb	Liquid-in-glass expansion bulb	Temperature	Most materials expand with temperature increases.	Mechanical displacement	Mercury thermometer
8	Temperature	From −60 C to 550 C	Fluid-in-metal expansion bulb	Fluid-in-metal expansion bulb	Temperature	Expansion of liquid or gas due to temperature rise increases pressure in a completely filled system.	Pressure	Bourdon tube thermometer
9	Temperature	From −25 C to 325 C	Vapor - pressure bulb	Vapor - pressure bulb	Temperature	In a partially filled liquid system the vapor pressure is a function of the temperature.	Pressure	Temperature controller
10	Pressure	From 0 to 10,000 lb per sq in.	Bourdon tube	Bourdon tube	Pressure	Expansion of liquid or increase in gas pressure in a curved closed tube tends to straighten it.	Mechanical displacement	Bourdon pressure gauge
11	Pressure	From 0 to 500 lb per sq in.	Bellows or diaphragm	Bellows or diaphragm	Pressure	Increased pressure inside a flexible bellows or diaphragm tends to expand it.	Mechanical displacement	Aneroid barometer or altimeter
12	Pressure	From 0 to 20 lb per sq in.	U tube	Liquid column	Pressure	Increased head in one leg of a U tube with liquid in it displaces the liquid.	Mechanical displacement	Manometer
13	Pressure	From 10 to 2,500 lb per sq in.	Piston	Piston	Pressure	A piston with a pressure on one end will move. When balanced by pressure on the other end, the balancing force is a function of the pressure.	Force or weight	Dead weight tester
14	Pressure	From 0 to 1,500 lb per sq in.	Piezoelectric crystal	Piezoelectric crystal	Pressure	Stress causes strain in a crystal and strained crystals become electrically polarized.	Potential	Crystal-type pressure gauge
15	Vacuum	From 0.1 to 2,000 microns	Calibrated volume system	Volume and piston	Pressure	A known volume of gas at a given pressure will compress to a new measurable volume at a known pressure. $pv = c$	Mechanical displacement	McLeod gauge
16	Vacuum	From 0.1 to 750 microns	Heated resistor	Temperature sensitive resistor and standardized-voltage source	Pressure	A voltage across a resistance heats it to a temperature which is a function of the gas and pressure surrounding it. The temperature corresponds to a definite resistance.	Resistance	Pirani gauge
17	Vacuum	From 1 to 500 microns	Heated resistor	Fixed resistor and standardized-current source	Pressure	A current through a resistance heats it to a temperature which is a function of the gas and pressure around it.	Temperature	Thermocouple vacuum gauge
18	Vacuum	From 10^{-4} to 1,000 microns (cold), 0–1 micron (hot)	Electronic tube	Electronic tube	Pressure	With a controlled ionizing means, the ion collector current is a function of the pressure for a given gas.	Current	Ionization gauge
19	Vacuum	From 0.001 to 1.0 micron	Moving vane and heater	Moving vane, fixed resistor, and standardized-voltage source	Pressure	The heater creates a level of molecular energy that is higher on the adjacent side of the moving vane than on the opposite side. This difference in energy exerts a torque on the vane which is a function of the pressure.	Torque	Knudsen gauge
20	Fluid flow		Fluid motor	Fluid motor	Fluid speed	A fluid flowing through a fluid motor will move the rotor.	Angular displacement	Gasoline flowmeter

Table II (Continued). Typical Primary Detectors for Measurement of Nonelectrical Quantities

	Quantity Measured	Range of Use	Name	Basic Elements	Input	Physical Effect Output = Kf (Input)	Output	Typical Application
21	Fluid flow		Orifice	Orifice	Fluid speed	A difference in pressure on opposite sides of an orifice exists where fluid flows through.	Differential pressure	Industrial flowmeter
22	Fluid flow		Pitot tube	Pitot tube	Fluid speed	A difference between static and total head is a function of the fluid and its velocity through a pitot tube.	Differential pressure	Aircraft airspeed indicator
23	Fluid flow		Variable orifice	Float and conical tube	Fluid speed	A float in a conical tube will assume a position to vary the orifice size as a function of the fluid speed. The position of the float is therefore a function of the speed.	Linear displacement	Rotameter
24	Liquid level		Float	Float	Liquid level	A light body will be buoyant in a liquid and its position is a function of liquid level.	Mechanical displacement	Float gauge
25	Liquid level		Diaphragm	Diaphragm	Liquid level	A diaphragm is deflected by the head of liquid above and provides a pressure in a closed system which is proportional to the liquid level.	Pressure	Hydrostatic-type liquid level gauge
26	Liquid level	From 0 to 50 ft	Capacitor	Varying dielectric	Liquid level	The capacitance of a capacitor is a function of the dielectric. With two dielectrics such as a liquid and air the capacitance is a function of the dividing line position.	Capacitance	Capacitance gasoline gauge
27	Mechanical displacement		Variable capacitor	Variable capacitor	Mechanical displacement	A change in the relative position of capacitor plates alters the capacitance.	Capacitance	Capacitor-type electric gauge
28	Mechanical displacement	From 0.015 to 30 mils	Variable inductor	Variable inductor	Mechanical displacement	Small changes in air gaps of magnetic cored inductors change their inductance.	Inductance	Electrolimit gauge
29	Mechanical displacement		Voltage divider	Variable resistor	Mechanical displacement	The resistance from a fixed to a variable contact on a resistor changes as a function of the variable contact position.	Resistance	Position telemeter
30	Angular displacement	From 0 to 360 deg	D-c Selsyn transmitter	Variable resistor and d-c source	Angular displacement	A voltage impressed at opposite diameters of a tapped circular resistor sets up a voltage distribution between various taps.	Potential distribution	D-c Selsyn
31	Angular displacement	From 0 to 360 deg	A-c Selsyn transmitter	Electromagnetic stator and rotor and a-c source	Angular displacement	An excited rotor inside a polyphase stator will set up a potential distribution in the stator in accordance with the angular position of the excited rotor.	Potential distribution	A-c Selsyn
32	Angular displacement	From 0 to 360 deg	Second harmonic transmitter	Permanent magnet, saturating coil and a-c source	Angular displacement	Unidirectional flux in a polyphase coil with an a-c saturated core will set up a second harmonic potential distribution dependent on the angular position of the unidirectional flux.	Potential distribution	Second harmonic telemeter system
33	Strain	From 20 to 30,000 microin. per in.	Strain wire	Strain-sensitive resistor	Strain	Strain on wire alters dimensions and resistance of wire.	Resistance	Wire strain gauge
34	Strain	From 0.015 to 30 mils	Strain electromagnet	Variable inductor	Strain	Strain varies air-gap in variable inductor to change its inductance.	Inductance	Electromagnetic strain gauge
35	Weight or force		Spring	Spring	Force	A spring deflects as a function of the applied force.	Mechanical displacement	Spring balance
36	Acceleration	From 0 to 40 g	Spring supported mass	Solid mass and spring	Acceleration	Acceleration moves a mass with a force which is proportional to the acceleration and deflection is controlled by the spring.	Deflection	Aircraft accelerometer
37	Acceleration	From 0 to 10 g	Movable plate and electronic tube	Movable plate, electronic tube and voltage source	Acceleration	In a vacuum tube if the plate is movable, the plate current is a function of the plate position with respect to the cathode. Elastically mounting the plate makes the plate current a function of acceleration.	Current	Vacuum tube acceleration pickup
38	Speed	From 100 to 5,000 rpm	D-c generator	Electromagnetic stator, moving permanent magnet and commutator	Angular velocity	Generated potential is a function of rpm	Direct potential	Magneto tachometer
39	Speed	From 100 to 3,600 rpm	A-c single-phase generator	Electromagnetic stator and moving permanent magnets	Angular velocity	Generated potential is a function of rpm.	Alternating potential	Alternating voltage tachometer system
40	Speed	From 200 to 11,000 rpm	A-c generator	Electromagnetic stator and permanent magnet rotor	Angular velocity	Frequency of generated potential is a function of rpm.	Frequency	Aircraft tachometer or railway type tachometer system

Table II (Continued). Typical Primary Detectors for Measurement of Nonelectrical Quantities

	Quantity Measured	Range of Use	Name	Basic Elements	Physical Effect: Input	Physical Effect: Output = KF (Input)	Output	Typical Application
41	Speed	From 200 to 5,000 rpm	Magnetic - drag disk	Permanent magnet rotor and eddy-current drag disk	Angular velocity	Rotating magnet reacts with eddy currents in disk to produce a torque which is a function of rpm.	Torque	Automobile tachometer
42	Speed	From 100 to 750 rpm	Fly-ball governor	Movable weights and springs	Angular velocity	Centrifugal force on weights can be balanced against a spring force to give a displacement.	Mechanical displacement	Steam turbine governor
43	Speed		Rotating mirror	Mirror and electric lamp	Angular velocity	Light projected on a rotating mirror is reflected as pulses, the frequency of which is proportional to rpm.	Frequency of light pulses	Electronic tachometer
44	Speed	From 0 to 90,000 flashes per min	Flashing light	Discharge lamp and variable frequency source	Angular velocity	The rate of light flashes is adjusted until the rotating object appears stationary because of stroboscopic effect. When this occurs the frequency of the source is a function of rpm.	Frequency	Electric stroboscope
45	Vibration velocity	From 0.001 to 40 in. per sec	Electromagnetic pickup	Permanent magnet and moving coil	Vibration velocity and frequency	A potential proportional to the velocity is induced in a coil moving in a permanent magnet field.	Potential and frequency	Vibration velocity meter
46	Vibration acceleration	From 10 to 5,000 g	Piezoelectric pickup	Piezoelectric pickup	Vibration acceleration	A potential proportional to the acceleration appears in a piezoelectric crystal when stressed by vibration forces.	Potential and frequency	Vibration acceleration meter
47	Vibration frequency	From 15 to 500 c	Vibrating reed	Spring and mass	Vibrational frequency	When natural and forced frequencies are equal the amplitude of vibration is maximum.	Mechanical displacement	Vibrating - reed-type vibration meter
48	Sound	From 20 to 120 db	Microphone	Piezoelectric crystal	Sound	Sound energy impinging on a crystal microphone stresses the crystal and the strains produce a voltage as a function of the wave shape of the sound waves.	Potential	Sound level meter
49	Illumination	From 1 to 100 ft-c	Photovoltaic cell	Photovoltaic cell	Illumination	Radiations on a photovoltaic cell results in an emf across the terminals.	Potential	Light meter
50	Illumination	Starlight to 50,000 ft-c	Photoemissive cell	Photoemissive cell. Voltage source	Illumination	Radiations on a photoemissive cell result in the emission of electrons.	Current	Phototube light meter
51	Illumination	From 0 to 0.25 ft-c	Photoconductive cell	Photoconductive cell	Illumination	Radiations on a photoconductive cell result in a change in electrical resistance which is a function of the radiation intensity.	Resistance	Infrared meter
52	Illumination		Black body	Black body	Illumination	Light radiations are absorbed and change the temperature of a black body.	Temperature	Thermocouple bolometer
53	Brightness	From 2 to 50 ft-L	Optical wedge	Wedge filter and electric lamp	Brightness	Light of a given brightness will emerge from a wedge filter at a mechanical position dependent on the input light brightness. The position of the wedge in which the emerging brightness agrees with a standard brightness is a function of the input brightness.	Mechanical displacement	Luckiesh - Taylor brightness meter
54	Light energy		Photoemissive cell	Photoemissive cell and d-c source and capacitor	Illumination	Current from a photoemissive cell is a function of the illumination and can be integrated to give light energy for the time interval.	Current	Lumen - second meter
55	Color	400 to 700 millimicrons	Monochromatic lights and photoemissive cell	Electric lamp, prism and photoemissive cell	Transmitted light of various wave lengths	The prism disperses the light to produce the monochromatic lights which are transmitted through or reflect from the color and the resulting light forms a spectrum as a function of the color. It can be compared with a spectrum of a standard.	Spectrum	Recording spectrophotometer
56	Cosmic, X-ray and radiations		Geiger - Muller tube	Geiger-Muller tube and d-c source	Radiations	Radiations, which ionize a gas, will allow electric conduction and certain vapors in the gas will quench the current.	Current	Geiger - Muller counters
57	Humidity	From 0 to 95 per cent relative humidity	Wet and dry bulbs	Liquid expansion bulbs and moist wick	Humidity	Evaporation from the moist wick lowers its temperature below that of the dry bulb. The difference between these temperatures depends on the humidity.	Differential temperature and dry temperature	Sling psychrometer
58	Humidity	From 0 to 100 per cent relative humidity	Variable temperature chamber with reflectors	Mirror and heating and cooling source	Humidity	The dewpoint of a gas is detectable by condensation on the mirror surface as the temperature is raised and lowered.	Temperature	Recording dewpoint meter
59	Humidity	From 15 to 100 per cent relative humidity	Moisture sensitive resistor	Moisture sensitive resistor	Humidity	Certain salts become moist in humid air and their electrical resistance is a function of humidity.	Resistance	Humidity indicator

Table II (Concluded). Typical Primary Detectors for Measurement of Nonelectrical Quantities

	Quantity Measured	Range of Use	Name	Basic Elements	Input	Physical Effect Output = Kf (Input)	Output	Typical Application
60	Humidity	From 15 to 100 per cent relative humidity	Heated moisture sensitive resistor	Moisture and temperature sensitive resistor and voltage source	Humidity	A voltage applied to a salt such as LiCl which is a conductor only when moist keeps temperature such that the saturated solution vapor is in equilibrium. The temperature is then a measure of dewpoint.	Temperature	Humidity indicator
61	Humidity	From 0 to 100 per cent relative humidity	Moisture sensitive expander	Moisture sensitive expander	Humidity	Some substances change dimensions with humidity changes.	Mechanical displacement	Human hair hygrometer
62	Humidity		Capacitor	Capacitor	Humidity	The capacitance of a capacitor is a function of its dielectric and this varies with moisture content and hence humidity.	Capacitance	Moisture content indicator
63	Viscosity		Constant speed rotor	Vessel and constant speed rotor	Viscosity	The torque on a plunger in a material spinning at constant speed is a measure of viscosity.	Torque	MacMichael viscosimeter
64	Viscosity		Cup and orifice	Vessel and orifice	Viscosity	The time for a given amount of liquid to flow through an orifice is a function of its viscosity.	Time	Saybolt viscosimeter
65	Viscosity		Constant torque rotor	Vessel and constant torque rotor	Viscosity	The speed of a rotor in the material when driven by a constant torque is a measure of viscosity.	Speed	Stormer viscosimeter
66	Viscosity		Falling body	Vessel and ball	Viscosity	An object in a liquid acted on by a known force will accelerate and move through the liquid at a speed which is a function of its viscosity.	Average speed	Falling ball viscosimeter
67	Chemical composition		Diffraction grating	Defraction grating and heat source	Electromagnetic waves	A heated body radiates typical frequencies depending on its composition. A spectrum of these frequencies is formed with a grating.	Spectrum pattern	Spectrograph
68	Chemical composition	Mass range 2 to 400	Mass spectrometer	Electrodes, electromagnets, electron tube, d-c source	Mass as ionized gas	A moving charged mass will follow a given curve if acted on by a field intensity. The curve is a function of the mass.	Mechanical displacement	Mass spectrometer
69	Time	0.1 sec up	Timing motor	Timing motor and a-c standardized frequency source	Time	A constant speed motor will move through a definite angle in a given time.	Angular displacement	Time meter
70	Time	1/4 sec up	Pendulum	Lever, mass, and energy source	Time	A pendulum makes a complete oscillation in a definite time.	Number of oscillations	Pendulum clock
71	Time	0.1 sec up	Balance wheel	Mass, energy storage spring, and energy source	Time	A balance wheel mechanism makes a complete oscillation in a definite time.	Number of oscillations	Stop watch
72	Time	10^{-7} sec up	Crystal oscillator	Crystal and a-c source	Time	A crystal under controlled conditions will oscillate at a constant frequency.	Integrated frequency	Frequency standard
73	Time	10^{-4} sec up	Tuning fork	Tuning fork, electromagnet, and a-c source	Time	A tuning fork vibrates at a constant frequency under controlled conditions.	Number of oscillations	Integrated frequency control instrument
74	Time	0.01 sec up	Vibrating wire	Wire vibrator, electromagnet, and a-c source	Time	A wire under controlled conditions vibrates at a constant frequency	Number of oscillations	Load frequency control
75	Magnetic direction	From 0 to 360 deg	Compass	Permanent magnet	Magnetic direction	The flux from a horizontal permanent magnet reacts with the horizontal component of the earth's field to produce a torque to turn the magnet into the earth's magnetic field. It will therefore indicate an angle between a given direction and magnetic north.	Angular Displacement	Remote compass
76	Magnetic direction	From 0 to 360 deg	Second harmonic generator	Polyphase coil, saturable reactor, and a-c source	Magnetic direction	A distributed polyphase winding around an a-c excited saturated core will have a second harmonic potential distribution induced in it as a function of the direction of unidirectional magnetic field cutting it.	Potential distribution	Aircraft automatic pilot directional control
77	Magnetic direction	From 0 to 360 deg	Induction coil	Rotating induction coil and motor	Magnetic direction	The voltage induced in a rotating coil will be a maximum when moving to cut a maximum of the earth's magnetic field.	Potential	Induction coil compass
78	Space direction	From 0 to 360 deg	Gyroscope in universal mounting	Gyroscope rotor and energy source	Space direction	A gyroscope acted on by no torques will remain with its spin axis in a fixed direction in space. It will therefore indicate the angle between a given direction and the space direction of the spin axis of the gyroscope.	Angular displacement	Directional gyroscope or bank and climb gyroscope
79	Geographical direction	From 0 to 360 deg	Gyrocompass	Pendulous gyroscope and energy source	Geographical direction	A pendulous gyroscope with its spin axis horizontal will tend to line its spin axis with the spin axis of the earth.	Angular displacement	Gyrocompass

Figure 4. Light meter

Figure 6. Single-phase var-hour meter

to their inertia) do introduce transients, it is necessary to analyze the transient characteristics and to know how they can be changed.

It should be understood that many quantities such as mechanical deflection, current, and potential are the inputs to primary detectors measuring that quantity, but they also may be the outputs of other primary detectors measuring entirely different quantities. For example, in Figure 4 the light cell has potential as its output. But potential can be the input to a primary detector which might be a permanent-magnet moving-coil mechanism. Mechanisms used as primary detectors in some cases may be used as intermediate means in other cases.

PHYSICAL LAWS AND EFFECTS

Nearly all physical laws have been used in measurement work, and many appear in primary detectors. Some of the important ones are listed in Table III. These laws, together with Newton's laws where mechanical motion is involved and Kirchoff's laws where electric networks are used, make it possible to set up the differential equations for the detector operation.

Figure 5. Thermal watt demand meter

MATHEMATICAL ANALYSIS

In order to obtain an expression for the relation of the output to the input, it is necessary to understand the physical laws and effects entering into the transfer. When these laws are known the determination of the transfer characteristics becomes a mathematical one, techniques for which are covered adequately in mathematical and engineering literature.[4] Standard classical, operational, or transform methods can be used to symbolize the transfer relations. In general, a complete understanding of operation is obtained only after a thorough and sometimes complex mathematical analysis. An adequate understanding is often obtainable, however, from simple qualitative examination of the input, the output, and the physical effect involved.

In general the passive physical elements such as inductance, capacitance, resistance, inertia, and heat capacity, in the interest of simplicity, can be considered constant over the measurement interval. For the same reason, only lumped and not distributed parameters usually are assumed. Mechanical or electrical analogues may be used as well as other artifices commonly applied to the solution of

Figure 7. Input-output characteristic of primary detectors

The output (y) of an ideal primary detector is, over the measurement range, a continuous, determinate, repetitive function of the input (x) only.

differential equations. When transform methods are used to express the ratio of the output to the input, this ratio in the primary detector can be called its characteristic function. It can be used to obtain the over-all measuring system characteristic. This is the relation between the end device operation and the quantity being measured. A typical application of this method is the analysis of the watt-hour meter mechanism in the appendix.

Figure 8. Detailed functional characteristics of watt-hour meter mechanism primary detector

This method not only offers a standard attack on the problem of understanding existing primary detectors, but it also provides the basis for the synthesis of the basic elements of proposed systems. Independent expressions for the transient relation and the steady-state relation between input and output can be obtained from the characteristic function of the detector.

CONCLUSIONS

The summary of this work in tabular form is intended for use in the educational field as well as in the specialized measurement engineering field. Since it is intentionally limited to a very general treatment of this phase of measurements, supplementary analysis is necessary for the complete intensive study of any particular system. A method of attack on this problem has been outlined. Finally, there is obvious need for a similar study of the remaining groups in the measurement sequence, namely, the intermediate means and the end devices, for a complete evaluation of this form of measurement analysis.

Appendix

If the detector is subdivided into its basic elements or schematically into functional blocks, a more complete understanding of results is possible. Such a breakdown is shown in Figure 8 for a watt-hour meter mechanism wherein 16 separate detail functions are carried out in three kinds of basic elements involving eight major physical effects.

A little study will show that at function number 8 and 9, torques are produced proportional to the input. Beyond this point the action is similar to a closed loop regulator since a feed-back circuit is utilized. Function 10 acts as an error detector initiating a change in response proportional to the difference of the inputs (T_1 plus T_2) and the feed-back torque (T_3). The output speed will be regulated until it is

proportional to the input T_1+T_2, at which time equilibrium conditions exist.

The simplified diagram in Figure 9 allows the characteristic function of the primary detector to be determined from the characteristic function of the separate blocks. If J is the disk inertia, K is the damping constant, and other terms as defined in the diagram,

$$\epsilon\left(\frac{1}{Jp}\right)=s \quad \text{.....as shown by Newton's laws in the diagram}$$

$$(T-Ks)\left(\frac{1}{Jp}\right)=s \quad \text{.....since } \epsilon=T-Ks \text{ as shown in the summation}$$

$$T-Ks=Jps \quad \text{.....by algebraically changing the position of } Jp$$

$$T=Jps+Ks=s(Jp+K) \quad \text{.by combining the terms with } s$$

$$\frac{S}{T}=\frac{1}{Jp+K} \quad \text{.....algebraically giving the speed to torque ratio}$$

$$\frac{\angle}{T}=\left(\frac{1}{Jp+K}\right)\left(\frac{1}{p}\right) \quad \text{.....since the "integration" block shows the angle equals the speed operated on by } 1/p$$

This demonstrates how the characteristic function $\angle/T$ has been obtained mathematically from the individual characteristic functions of the blocks in the diagram.

Electrical Progress in the Textile Industry

F. D. SNYDER
ASSOCIATE AIEE

THE textile industry is probably the oldest of all industries. A study of its history and development is a study of the history and development of civilization itself. Long before electric apparatus of any kind was developed it had progressed to a stage of perfection that many of the processes employed over a hundred years ago are still in use today. Because of this high degree of mechanical development the electrical industry was for many years not pressed to contribute its share to the industry. While it is true that electric motors found early use in the textile industry, this was in the nature of a prime source of power to a purely mechanical machine. The motor was attached to a shaft on the machine and any means of using and controlling its power was done mechanically.

Within recent years electrical applications in the textile industry have made steady progress. Now, many machines and processes get their prime motive power not only from electric motors, but special motor characteristics, controls, and other electric apparatus perform many worthwhile functions. With the use of proper electric equipment, mechanically complicated processes can be improved, simplified, and done more economically. With so many different machines used in the textile industry it would be difficult to describe all the electrical details employed. There are, however, a number of basic electrical functions which apply in various combinations to many of the textile machines, and it is the purpose of this paper to describe and explain the more important. Special motor characteristics to take care of exacting machine operating conditions, controlled acceleration, controlled deceleration, various types of variable speed operation, exact tension control, exact speed control, electronic protection devices, all contribute to electrical progress in the industry. A description of actual applications shows how various results are achieved. It also becomes apparent that many combinations of electrical functions can be made to meet the requirements of other textile machines.

Paper 48-114, recommended by the AIEE general industry applications committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 29, 1948; made available for printing February 16, 1948.

F. D. Snyder is with the Westinghouse Electric Corporation, Boston, Mass.

General Purpose Applications

There are and always will be a number of applications where a motor is used only as a source of power to turn a shaft at constant speed. For such applications efficient, safe and maintenance-free electric equipment is the prime requisite. The self-cleaning squirrel motor available for this purpose is so designed that dry lint will pass readily through the motor and it seldom needs attention. For this, and other motors used in the textile industry, a permanently sealed bearing lowers bearing maintenance cost and its use eliminates the danger of a soiled product from grease or oil.

For applications where the lint is very oily or where for other reasons the self cleaning open motor cannot be used, a new screened-type motor with large screen area is available. This large screen area permits satisfactory operation even if considerable lint has accumulated on the screen, because of the extremely low-air velocity through any unit area of the screen. In some cases totally enclosed motors are necessary.

These, however, are in the nature of mechanical improvements and developments and, while they are of importance to the textile industry, they do not contribute to the actual control of a machine or process and, therefore, will not be emphasized. It is important, nevertheless, that the improved mechanical features of motors and controls for textile plant operation be utilized in building electric apparatus for all types of applications.

Controlled Acceleration

Many textile machines such as roving and spinning frames, twisters, woolen cards, and others require no special features of the motor drive other than the provision of slow, smooth acceleration to a standard squirrel cage motor. Resistance-type cushioned starters of various kinds are now being used extensively; each type designed to perform desired functions.

For cotton roving frames an automatic type is used which will cut out the resistance when approximately full speed is reached. For twisters and many kinds of winders the control is so arranged that the resistance is in the motor circuit only while the operator keeps the start button depressed. Woolen cards present a different problem. A low torque is required initially to take up any slack in the drive and then be built up to maximum in order to break static friction. After the card starts to move, the torque must be reduced again to avoid undue stress as the high pullout torque point of the motor is reached. An automatic starter for squirrel cage motors on woolen cards provides these features by inserting and removing resistance in the proper sequence.

A more satisfactory type of drive for a woolen card employs a suitably protected slip ring motor controlled by a motor-operated secondary rheostat. This gives smooth and shockless acceleration from standstill to top speed and also affords means for some variation in production speed. The same type of drive is used on wool and worsted ring spinning frames for smooth acceleration and for varying the spinning speed. The special control developed for these applications will permit the operator to preset to any desired speed and acceleration will always be at the same rate.

Figure 1. Instantaneous kilowatt input to a loom motor for each position of the crankshaft of a typical loom

Figure 2. Curves showing peak loads of various loom motors operating the same loom at various speeds

Figure 3. Curves showing average loads of various loom motors operating the same loom at various speeds

Loom Motors

With the improvement in loom design, making speeds up to 220 picks per minute practical the loom motor becomes a good example of the benefit in the way of performance and economy that can be derived from proper motor characteristics. The curve in Figure 1 shows the instantaneous power requirements for each position of the crankshaft during the operating cycle of a particular loom operating at 180 picks per minute. This shows the fluctuation of power input to the motor from 2.4 kw maximum to a 0.3 kw regenerative. These power peaks will vary as the loom speed varies but they are also affected by the design of the motor as shown in Figure 2 which indicates the maximum power input peaks to various motors all operating the same loom and the manner in which these peak loads vary as the speed of the loom is varied. Figure 3 shows the average power input to these same motors operating the same loom at different speeds.

Curve *A* in Figures 2 and 3 is for a loom motor that was perfectly satisfactory at 150 picks per minute. Curves *B*, *C*, and *D* are for loom motors all with different flywheel effect, different slip or speed torque curves and different pull-out torque. It is apparent from these curves that a substantial saving in power consumption can be made by choosing a motor with the proper characteristics and the peaks can be held well below its pull-out point.

Curve *D* is for a motor having a very high flywheel effect and comparatively low slip. Obviously, this motor should not be used for loom speeds much below 200 picks per minute. The motor represented by curve *C* has the best operating characteristics for looms running up to 190 picks per minute. It is interesting to note that all the motors represented have within one per cent of the same efficiency when carrying steady loads between 1 and 1.5 horsepower.

Warp Knitting Machines

A motor drive for a warp knitting machine should provide low torque for slow and accurate jogging during setup and adjustment periods. Further, it should provide rapid acceleration during regular starting in order to avoid starting marks together with fast and reliable deceleration to avoid stop marks.

The jogging torque is obtained by resistor-type cushioned starting. For normal starting the full voltage starting torque of the motor is generally sufficient. In some cases, however, a torque build-up is required and obtained in the same manner as explained later under drives for wide-shuttle type looms.

For stopping, solenoid or spring-operated mechanical brakes are not satisfactory because they wil not remain in adjustment and require excessive maintenance. Reversing the power to the motor in conjunction with a zero-speed switch is not satisfactory because it is impossible to decelerate to a complete stop and because the motor may reverse and damage the machine. To achieve successful rapid and positive deceleration a d-c voltage is applied to two leads of the squirrel cage motor. Figure 4 shows a family of curves for a five-horsepower 4-pole 220-volt 3-phase squirrel cage motor and indicates the decelerating torque obtainable with different values of direct current. The value of braking torque varies for different motors but the curves give an indication of what may be expected. Curves *A*, *B*, *C*, and *D* are for 10, 20, 30 and 40 amperes direct current, respectively, through two phases of the 5 horsepower motor having a full load current rating of 12.5 amperes. The full load torque of this motor is 15 pounds at 1-foot radius and from the curves it may be seen that the braking torque may go up to over eight times the full load running torque.

This type of braking is particularly desirable because the braking torque drops off very rapidly as the motor speed approaches zero.

The basic schematic diagram of the control scheme used is shown in Figure 5. For jogging, the motor is connected to the line through the adjustable resistors *R1*, *R2* and *R3* by means of contactor *A*. For running, contactor *M* provides full voltage to the motor immediately. When stopping the machine contactor *M* drops out and by the use of a suitable timing relay contactor *B* picks up momentarily and applies direct current to the motor through the rectox rectifier and the resistors *R2* and *R3*. The amount of braking can be adjusted by moving the taps on these resistors. With this scheme the motor always comes to a definite stop and it cannot reverse even though the direct current should remain on the line. The timing relay is set so that contactor *B* will drop out just after the machine has stopped.

Dressing Reel Drive

The high-speed dressing reel used in the woolen industry consists essentially of a cylinder about four feet in diameter and from 8 to 15 feet long. A sufficient number of ends or threads for a loom beam are wound onto it, section after section. The sections are built up by pulling the ends from a creel or stand on which are mounted as many individual spools of yarn as there are ends in a section. The following are the requirements of this drive:

1. The reel must start slowly until all slack yarn is taken up.
2. It must provide a variable speed of not over two-to-one.
3. When a thread breaks or a yardage counter indicates a stop, the reel must stop within one half revolution in order that a broken thread is not lost on the reel.
4. As soon as the reel has stopped it must be free to be moved by hand.

The manner in which this is accomplished is shown in Figure 6. The motor

chosen is of the slip-ring type which is well adapted to provide the two-to-one speed range and also the very slow start to allow any slack yarn to be taken up. The control is arranged so that when the operator presses the start button, contactor M will pick up but contactor A will remain open as long as the button is held down. With contactor A open the secondary resistance remains in the circuit and the motor starts slowly. As soon as all slack is taken up and the reel begins to accelerate, the operator releases the start button which picks up contactor A and allows the reel to come up to the preset speed as selected by means of the rheostat.

Stopping the reel in half a revolution requires such a high torque that it cannot be safely transmitted through the drive shaft. This is solved by the use of two solenoid brakes, one at each end of the reel. Braking torque is also provided by the motor using direct current as previously explained. As shown in Figure 6, to initiate stopping, contactors M and A are dropped out and a timing relay picks up contactor B which supplies direct current, through the rectox, to the two-brake solenoids and two phases of the motor winding, all in series. Contactor B drops out after the reel has stopped, releasing all braking action and allowing the reel to be rotated by hand. When an end breaks, stopping action is initiated by a multiple-unit electronic stop motion relay that will be discussed later.

Jack Spool Drive

An improved spooler recently developed has operating requirements similar to the dressing reel except the stopping period, from the time that an end breaks to dead stop, must be not more than two revolutions of the motor. The machine must start slowly. An operating speed range of not over two-to-one is required.

The motor chosen is again the slip ring type which provides the slow starting feature and a two-to-one speed range. The inertia of this machine is not very great and the braking torque available by applying direct current to two leads of the motor primary is found sufficient to stop the machine well within two revolutions. However, too much time is lost before braking action begins with the scheme of dropping out the line contactor and then picking up the braking contactor.

The use of the arrangement shown in Figure 7 provides satisfactory braking by saving the pickup time of a braking contactor and has the following sequence of operation. When the start button is pressed contactors M and B both pick up

Figure 4. A family of curves showing the braking torque developed by a 5-horsepower 4-pole squirrel cage motor when direct current flows through any two legs of its 3-phase winding

and contactor A stays open. The slip-ring motor will start now with all the rheostat resistance in the motor secondary and the acceleration will be slow. When the start button is released contactor A picks up and the motor will accelerate to the speed selected by the rheostat.

The stop button, or the protecting device actuated by a broken end, will instantly drop out contactors B and A but contactor M remains closed. The full-wave rectox rectifier will supply direct current to the motor primary and start the braking action at the instant contactor B opens. A timing relay drops out contactor M and removes all power after the machine has come to rest.

Shuttle Type Looms Without Clutches

Large shuttle type looms used for the manufacture of paper mill felts, carpets, and other products have, until recently, required a friction clutch type of drive for two main reasons. First, it was the only sufficiently fast way to accelerate the loom to full speed before the shuttle is thrown across the loom the first time. Second, it was necessary in order to avoid the fly-wheel effect of the motor and gears when a protection stop is required. During this protection stop, which is required when a shuttle does not get across the shed, the loom is stopped instantly by engaging dogs, or fingers on the moving lay with the stationary breast beam. By releasing the clutch at the same instant the motor and gears are free and the dogs have to absorb only the energy from the loom itself. This, on these heavy looms, is still sufficient so that the protection stop frequently causes loom breakage. The clutch has also been desirable to allow the

Figure 5. Schematic diagram of control for a warp knitting machine

operator to jog the loom accurately during loom fixing or set-up operations.

A drive recently developed will operate these large looms without clutches and will go through the protection stopping without shock to the loom. Variable speed is not required so a squirrel-cage type of motor is used. The basic schematic diagram of the control is shown in Figure 8, and the various functions are achieved in the following manner.

To get the required rapid acceleration a squirrel-cage motor with windings designed for Y-connection operation, is used. All the phase leads are brought out and shown as T_1, and T_4, T_2 and T_5, T_3 and T_6. When the start button is pressed contactors B, D, and M, pick up in the order named. This connects the motor winding

Figure 6. Schematic diagram of control for a dressing reel

Figure 7. Schematic diagram of control for a jack spool

Figure 8. Schematic diagram of control for large-shuttle type loom

in delta to the line so that each phase winding is subjected to 1.73 times its normal rated voltage and a high starting torque is produced. On a particular 5-horsepower, 4-pole squirrel-cage motor tested the Y-connected torque on line voltage is 29.5 pounds at one foot for starting and 39 pounds at one foot for pullout. With the delta connection on the same motor these figures become 88.5 pounds and 117 pounds respectively. After the start button has been pressed a timing relay allows the motor to operate delta for a time long enough to permit complete acceleration, after which it drops out contactor *D* and picks up *Y*, connecting the motor winding in wye for normal operation.

When the stop button is pressed, or if the protecting switch functions because the shuttle has not arrived in the opposite shuttle box at a precise instant, contactor *B* drops out. This impresses a d-c voltage across two of the motor leads through the full-wave rectox rectifier and braking torque, as shown in Figure 4, is developed. The braking torque can be varied by adjusting the resistor *R1* and *R2*. With this scheme the loom is easily brought to rest in ample time for protection stop, smoothly and without shock. Contactors *D* and *M* drop out after the loom has stopped.

While the clutch type of drive provides only forward jogging this drive provides jogging in each direction. When the jog button is pressed contactors *Y* and *B* and either *F* or *R* pick up, depending on whether the forward or reverse jog button has been pressed. The motor is connected in its conventional, normal torque, Y-scheme and two of the motor leads are connected to the line through resistors *R1* and *R2*. By adjusting the taps on these resistors the motor can be adjusted to produce the correct amount of torque for slow and accurate jogging.

Axminster-Type Carpet Loom Drive

A complete drive for an Axminster-type carpet loom has been developed using two separate motors. The overhead-warp chain is driven by a squirrel-cage motor. Except for numerous limit switches properly interlocked to obtain the correct sequence of operation there is nothing about it worthy of consideration here. The drive which operates the loom itself has unusual features.

The Axminster loom uses a needle instead of a shuttle and should accelerate slowly compared to the shuttle-type of loom. A very slow continuous speed is required. Stopping must be fast but the decelerating torque should decrease rapidly as zero speed is approached so that the needle cable will not stretch and cause the needle to bounce backward a short distance after the loom has stopped. A variable operating speed is also required. The power requirements of an Axminster loom varies for a loom cycle somewhat in the same way as it does for an ordinary loom as shown in Figure 1. Therefore, a motor is desirable which has a drooping speed torque characteristic in order that the flywheel effect of the motor and the loom parts can furnish the peak power requirements. To accomplish this, a series d-c motor and a motor-generator set with a series-type generator is used with a special control as shown in Figure 9. It is general knowledge that a series generator feeding a series d-c motor provides an excellent variable speed drive with good regulation. It has many inherent qualities which, by proper control, are advantageous in the operation of an Axminster loom.

Contactor *M* connects the a-c motor of the motor-generator set to the a-c supply and this contactor remains closed at all times except during complete shutdown such as at the end of a working period. With the motor-generator running and the loom shut down, contactors *C* and *B* are picked up. This short-circuits the generator series field and sets up a circuit from the generator armature through the motor series field and resistor *R2*. The generator field, however, has such a low resistance that some current will flow through it and resistor *R1* is used to limit the current and thereby prevent the generator from becoming self-exciting with the *R2* resistance load, and yet provide sufficient field flux to aid the residual voltage so the motor series field will have roughly 30 per cent of the motor full load current flowing through it

When the jog button is pressed contactor *A* will pick up and impress a voltage across the motor armature equal to the drop across resistor *R2* causing it to rotate instantly since its field is already energized and the build-up time of the field has been saved. When the jog button is released, contactor *A* drops out and the motor stops by dynamic braking.

To obtain a continuous slow speed, con-

Figure 9. Schematic diagram of control for the main drive of an Axminster loom

Figure 10. Schematic diagram of variable voltage armature circuits for a slasher drive

tactor *A* picks up and then *B* drops out. This provides a slightly higher speed than the jogging speed since resistor *R2* is no longer in the circuit and the exact speed is determined by the setting of resistor *R1*. Since the slow speed does not have to be exact, the setting of resistor *R1* required to obtain the correct current through the motor field at standstill, will be satisfactory.

For high-speed operation contactor *A* picks up and then contactors *C* and *B* drop out in that order. The current from the generator will now divide between the generator series field and the speed-control rheostat. Due to the time constant, the voltage build-up on the generator will be slow and the motor will, therefore, build up its torque slowly and accelerate slowly. The actual speed of operation is determined by the setting of the speed-control rheostat. During the high-speed operation the sudden peak loads develop more rapidly than the generator voltage can build up to compensate for the increased load so that the motor slows down and the flywheel effect provides the peak. During this interval, the generator voltage is building up, when the load peak has passed, the motor will be restored quickly to its original speed.

When the stop button is pressed contactor *B* closes at the same instant contactor *A* opens and contactor *C* closes immediately after *A* has opened. Closing contactor *B* places a high voltage across the motor series field and resistor *R2*. The motor field builds up rapidly and since the motor armature is short-circuited through resistor *R3* strong dynamic braking results. Excessive current through the motor series field and generator armature is avoided since contactor *C* picked up and short-circuited the generator field, at which time the generator voltage immediately started to drop. However, long before the current through the motor field has dropped down to its permanent standstill value dynamic braking will have stopped the loom motor.

Slasher Drive

Slashers come under the general category of textile range drives. A range drive may be described as a drive for a process where two or more sections or machines are driven by individual motors controlled so that the various sections will handle a continuous flow of cloth or yarn and provide, at all times, the tension or stretch desired between sections. Because most range drives require a wide range in speed the variable voltage d-c type of drive now is almost universally used. Into this scheme can be incorporated such devices as the Rototrol or rotating regulator, tachometer generators and others. Electronic conversion from alternating to direct current with its inherent characteristic of accurate controls is used also at times instead of motor-generator set. Range drives have improved rapidly during the past few years, but probably the greatest advances have been made in the slasher drive which requires an extremely accurate control.

A slasher is a machine which takes yarn from a series of spools or beams, combines the ends into a single sheet of yarn, runs the sheet through a starch or sizing bath, then through or over a drying medium and finally winds the yarn onto a loom beam. For the purpose of describing such a drive we have chosen a slasher with four motors driving the size box rolls, the dry cans, the front delivery rolls and the beam or take-up spool. In order to meet all the requirements a d-c variable voltage drive with a number of unusual features, is used. These will be described hereafter and the basic diagram is shown in Figures 10, 11 and 12.

A range of speed is required in the order to 2 to 5 yards per minute for creeping and of from 10 to 90 yards per minute for production. This wide speed range is obtained by a variable armature voltage on all the motors. Figure 10 shows the motor armatures connected to the variable voltage generator and whenever a different operating speed is required the voltage to all the motor armatures is raised or lowered. The variable voltage generator is equipped with a main shunt field which is used to control the voltage over the production speed range and an auxiliary shunt field which is used to control the voltage at stalled tension and for creeping speeds under the several conditions as will be explained later.

The wind-up beam must be core-driven

Figure 11. Schematic diagram of field excitation and control circuit for a slasher drive

Figure 12. Schematic diagram of Rototrol or tension regulating circuit of the beam motor for slasher drive

Figure 13. Schematic diagram of a single-unit type of electronic stop motion relay

by the beam motor. Therefore, for any given production speed the motor speed must be variable over a 6-to-1 range to compensate for build-up from empty to full speed and simultaneously hold a constant yarn tension over this range. To maintain a constant tension at a particular yarn speed it is only necessary that the beam motor develop a constant horsepower in going from the empty to the full beam speed. At a given yarn speed the armature voltage remains constant, consequently, if the current of the beam motor is kept constant, it will automatically develop a constant horsepower and, therefore, wind up the yarn at a constant tension. This is accomplished by using a Rototrol or rotating regulator to supply the field current for the beam motor as it operates through its 6-to-1 speed range by field control. Figure 12 shows the schematic diagram of the Rototrol circuit. The Rototrol armature is driven by the a-c motor that drives the variable voltage generator and the constant voltage exciter. In production contactors *D* and *B* are closed short-circuiting out resistor *R21*. Resistor *R22* is adjusted so the total resistance of the circuit becomes a value that permits the series or self-energizing field of the Rototrol to maintain any desired current through the shunt field of the beam motor once that value is established. The Rototrol has two other fields shown as the Rototrol control field in Figure 10 and the Rototrol pattern field in Figure 11. The Rototrol control field is a measure of the current in the beam armature and is connected to help the self-energizing field. Contactor *LV* in Figure 11 is always picked up when the slasher is in operation and the Rototrol pattern field is set up to oppose the control field. Assume that the run and creep tension rheostat in Figure 11 is set to a point where the amount of current that will flow through the pattern field will require ten amperes through the beam armature in order for the control field to balance exactly the pattern field. Then, if for some reason, there are not exactly ten amperes flowing through the beam armature, the control field will help or the pattern field will buck the self-energizing field until the beam shunt field is of the correct value to make the motor operate at ten amperes. The control and pattern fields are now neutralized and the self-energizing field maintains the proper beam motor shunt field current. As the yarn is wound onto the beam and the diameter increases, the beam motor current will go slightly over ten amperes. The control field will, therefore, overbalance the pattern field and aid the Rototrol series field causing its voltage to rise and strengthen the beam motor field. The speed of the motor will tend to reduce until the ten amperes are again obtained. This regulation continues until the beam is full.

The tension of the yarn as it is wound onto the beam is always greater than the friction load of the entire slasher. Therefore, the delivery roll motor must always hold back and operate as a generator. The drive ratio between this motor and the delivery roll must be selected properly so that the motor can act as a generator while the beam motor is acting as a motor. The delivery roll shunt field is excited from the exciter bus as shown in Figure 11.

As the speed of the drive is varied by a change in armature voltage it is necessary that the torques of the several motors remain at the same values if the yarn tensions are to remain constant. At the higher voltages this is true, but as the lower voltages of creeping speed and the lower operating speeds are reached, the resistance drops of the motor armatures become a large percentage of the total voltage. Since this resistance drop percentage is different for the several motors, their torque relationships change and, therefore, the tensions change. To overcome this, where necessary, a booster generator is placed in series with the beam motor and a bucker generator in series with the delivery roll motor. The shunt fields of these two generators are shown in Figure 11 and they are adjusted automatically as the run and creep tension rheostat is adjusted, so that both generators will produce the correct voltage to overcome the armature resistance drop of their respective motors at all tension settings.

The dry can and size box motors usually operate at low load and, therefore, the armature resistance drop does not have as pronounced an effect as it does on the other motors. The correct tension can be maintained usually between size box and dry can, and dry can and delivery roll by the use of resistor *R6* in series with the motor armatures, as shown in Figure 10, to give the motors a slight droop in the speed-torque curve and by providing rheostats for their shunt fields, as shown in Figure 11, so the operation of the individual motors can be changed from motoring to generating as required. For very exacting conditions a booster may be used for these motors. Ammeters are provided for all of the motor armatures which serve as a guide to the operator for setting up.

Besides maintaining constant tension during production speeds, other exacting conditions have to be met in a slasher drive and these are accomplished as follows.

Stalled Tension. If for any reason the slasher is stopped with yarn on the beam there must remain sufficient tension on the beam motor to hold the yarn tight but not sufficient so that the machine will creep. When stalled tension is desired contactors *D* and *S* are open but *B* remains picked up. With these conditions from Figure 10 the beam motor is connected to the generator but the other motors are open. The accelerating rheostat, Figure 11, has been moved by the rheostat motor to the position of the solid arrow at the left and the main generator shunt field voltage becomes zero. With contactor *D* out, the generator auxiliary field is energized through the stalled tension rheostat. Figure 11, and is connected so that the auxiliary field may vary from positive to negative which may be required to partially overcome residual voltage of the variable voltage generator.

With contactor *B* open it can be seen from Figure 11 that the beam booster shunt field, the delivery roll bucker shunt field and the Rototrol pattern field are open. The Rototrol circuit, Figure 12, has resistor *R21* inserted in the line which detunes the circuit so that it is no longer self-energizing and, therefore, will not attempt to regulate for constant current. The beam motor produces a torque depending on the setting of the stalled tension rheostat. Changing this rheostat to obtain a higher generator voltage will cause more current to flow through the beam motor armature. This in turn causes more positive excitation for the Rototrol from its control field and a stronger beam motor field, and thus, the torque of the beam motor increases both

because of a change in armature voltage and field strength.

Hold With Tension Off. When a full beam is doffed the beam tension must be removed. At this time the delivery roll motor must develop torque to keep the yarn under tension from the delivery roll back through the rest of the machine. To do this contactor *B* drops out and *D* picks up and the delivery roll motor is energized. The correct armature voltage to hold the slasher is provided by adjusting the hold tension-off connection on resistor *R7*, Figure 11, which adjusts the voltage on the generator auxiliary field.

Creep With Tension Off. At times, it is necessary to move yarn through the slasher with the beam motor off. This requires a slightly higher voltage than the preceding hold position and this is accomplished by picking up contactor *R*, Figure 11, which adjusts the generator auxiliary shunt field through the creep tension-off point of resistor *R7*. At the same time contactor *S* picks up so the size box and dry-can motors can develop torque, and with contactor *B* open the delivery roll motor shunt field is weakened so it will tend to stay ahead of the dry can and size-box motors and maintain tension.

Creep With Tension On. With the warp in place on the beam and under tension, pressing the creep button will put all the motors on the line. The main generator shunt field remains at zero voltage and the auxiliary field provides excitation for the necessary armature voltage by the proper setting of the creep tension-on point of resistor *R7*. At this time the Rototrol is functioning and the beam motor and delivery roll motor have their boosting and bucking generators respectively connected into the circuit. Tensions are, therefore, maintained accurately at the same value as when the slasher is running at production speed.

Acceleration. Acceleration from zero or creeping speed to operating speed is accomplished by the motor operated accelerating rheostat, Figure 11. During this period the accelerating rheostat moves from the solid arrow position at the left, Figure 11, to the dotted arrow position at the extreme right. The main generator shunt field builds up from zero to the value set by the speed regulating rheostat. During this time contactor *AR* picks up which operates the rheostat motor, Figure 11. It also inserts resistance *R2* into the Rototrol control field which has the effect of requiring more current through the beam armature to balance the setting of the Rototrol pattern field. The slasher accelerates with the beam motor being controlled by the Rototrol to produce a higher torque than its pattern field setting so that part of the torque is available for acceleration and part to maintain the required tension.

In order to get about the same rate of acceleration regardless of the setting of the rheostat motor is automatically decreased as the speed regulating rheostat is set for higher speeds. Figure 11 shows the manner in which the armature voltage of the rheostat motor is caused to vary inversely as the voltage setting of the generator main field as it is determined by the creep and run tension rheostat.

Deceleration. When it is desired to decelerate to either creep or stop, the power remains on all motors while the rheostat motor moves the accelerating rheostat back to zero voltage position. If deceleration is from run to creep all motors remain on the line and continue to operate at the creeping voltage. If deceleration is from run to stop contactors *D* and *S* drop out and disconnect the delivery roll, dry-can and size-box motors, but enough voltage is left on the beam motor to maintain stalled tension. The speed of the rheostat motor during deceleration is determined by the adjustment of resistor *R15*, Figure 11.

Note that positive stopping of the rheostat motor is provided by dynamic braking in both the accelerating and decelerating directions.

Emergency Stop. An emergency quick stop is available by dropping out contactors *B*, *D*, *S*, and *LV*, Figures 10 and 11. This provides strong dynamic braking of the beam and delivery roll motors and a full field is insured for the beam motor since the Rototrol pattern field is reversed. This stop is for emergency only and will not maintain yarn tension.

Electronic Devices

The textile industry is alert to the possibilities presented by the use of electronic devices. Silk and synthetic yarn mills clean air by electrostatic means before it is circulated through dryers. Electrostatic means are used also to clean all the air in many weave sheds and spinning and winding rooms. Dielectric heating is used for twist setting of various yarns and to dry yarns under certain conditions. Ultraviolet generators are used to aid chemical reaction of some finishing processes. Electronically operated and controlled d-c motors are used for many applications.

Electronic relays are being used for the safe, fast and positive stopping of machines when single threads break or where bobbins in loom shuttles run out. Figure 13 shows a single-unit type of electronic relay. The drop wires, which are small open metallic contacts, are held up by individual threads and while all the drop wires are held up the grid of the thyratron is held negative so the tube cannot fire. As soon as a thread breaks and its drop wire falls, the grid becomes positive and the tube fires and picks up the relay. This action is dependable even though the drop wire contact is made only for a few micro seconds and the contact resistance, due to dirt and corrosion, is as high as 30,000 ohms. The voltage across the open drop wire is about 10 volts with one side grounded, so open contacts are not dangerous. At the time the drop wire contact is made the current is so small that there is no arcing or burning on the lightest of drop wire or contact making schemes.

Figure 14. Schematic diagram of a multiple-unit type of electronic stop motion relay

A similar electronic relay is shown in Figure 14, except this is a multiple-circuit type. As many groups of drop wires as are desired are connected as shown, one group to *D1*, one to *D2*, and so on, using as many thyratrons as there are drop wire, or indicating groups. If a contact is made at *D1* its thyratron will fire and pick up the relay and also illuminate the indicating *Lamp-1*. Since the thyratrons are operated by direct current once they are fired they will remain conductive and keep the relay picked up and the lamp illuminated even though its drop wire cir-

cuit is opened. The relay is dropped out by a reset circuit in series with the relay coil, not shown in Figure 14.

When any one of the drop wire circuits, such as *D1*, has fired its thyratron, current will flow through resistor *R3* and because of the voltage drop in *R3*, the cathodes of all the thyratrons will become more negative than the grounded lead of all the drop wire circuits. Therefore, after the relay has picked up and stopped the machine, should any or all of the remaining drop wires close, they cannot cause their respective thyratrons to fire and only the lamp corresponding to the drop wire that first made contact will be lighted and the operator will know exactly where the trouble originated.

Electrical progress in the textile industry has already contributed to the production of better textile products and to the production of these products at costs so they can come within the reach of more and more people. The close co-operation between the textile mills, the textile machinery builders and the electrical manufacturers will continue to produce results to the end that more and better textiles and textile products will be available to all people everywhere.

Discussion

R. J. Demartini (General Electric Company, Schenectady, N. Y.): The paper does an excellent job of pointing up the manner in which electric equipment is being used in increasing measure to solve difficult processing problems in the industry. What comment is in order here must be largely in the nature of additions to what has already been said so well.

Loom Motors

From the curves of kilowatt input versus picks per minute (Figures 2 and 3 of the paper) it is apparent that by proper combination of motor inertia and electrical characteristics, a loom motor may be designed for optimum performance for a specific application. To this should be added the statement that, however good the electrical characteristics of a motor driving the pulsating loom load may be, addition of inertia results in gains in three directions.

1. Losses are less, hence power consumption is less and in some cases it becomes possible to use smaller motors.

2. Speed variation over the operating cycle is less, hence what the fixer refers to as the "feel" of the loom is improved.

3. Average power factor is better.

It is for this reason that rotors of most loom motors have greater inertia than do those of general purpose machines. Economics, however, limit the designer in the extent to which he can go in securing Wk^2 by way of larger rotors. For these reasons, much work has been done on the development of loom motors with flywheels added. See Figure 1 of the discussion.

This is not to say, however, that an external flywheel should be added to every loom drive. Rather, each application should be considered individually and the cost of such an addition should be balanced against the value of benefits to be gained.

Warp Knitting Machines

Operating advantages realized from electric braking of warp knitting machines have won general acclamation in the industry. Although there are theoretical advantages to be gained from the use of d-c dynamic braking as opposed to plugging, in the several installations of plugging control that method has proved to be highly satisfactory. Today's plugging switch design incorporating the "alnico" permanent magnet mechanism is a very reliable device. The rate of deceleration by this method is equally as good as that obtainable by d-c dynamic braking in this application. Considerably fewer devices are required, and as a consequence the cost of control is only about one-third of that of the competitive method. Maintenance too is reduced.

Axminster Carpet Loom Drives

Justification for the use of an adjustable speed drive on an Axminster carpet loom lies largely in the fact that mechanical adjustments on this machine are critical and must be made at various reduced speed levels. Mills also appreciate having a means for increasing loom speed in small increments as machine cams and other elements are gradually improved. Having proper operating characteristics during the normal run part of the cycle as pointed out in the paper, is of great importance to the mill. However, recognition must be accorded the fact that mills engaged in Axminster carpet weaving differ in the manner in which they expect the drives to operate. It is, therefore, important that there be incorporated in the design a degree of flexibility which will insure that the electrical equipment will be capable of satisfying demands of the various schools of thought on Axminster loom operation.

Consideration of the features incorporated in such electronic motor controls as the *Thymo-trol* reveals that these offer certain advantages not present in the motor-generator set drive as described. These are:

1. The rate of acceleration is adjustable. In this regard the requirements of two plants of a single company have been found to differ considerably.

2. The amount of droop in the speed-torque characteristic of the drive, though fixed by machine characteristics in the motor-generator set equipment, in the electronic drive is adjustable by setting of the *IR* drop compensation potentiometer.

3. With the field heating, there is an inevitable speed change in the drive described (as much as several picks per minute). A field current regulator, which is part of the electronic drive prevents this.

4. The design of the series generator drive requires that the generator be located close to the loom drive motor, in the lint laden atmosphere. Unless a totally enclosed set is employed, involving large, costly derated machines, there is introduced a fire hazard in the weave shed. The electronic rectifier has no commutator, and hence this problem is nonexistent.

Electronic Devices

Features of electronic control have been perhaps over-glamorized in its relatively few years in industry. Many mill maintenance people are as yet unfamiliar with such equipment. For these reasons good electrical application engineering has concentrated its efforts in those fields where a job can best be done or can be done only with the use of electronic control. Such criteria are hardly restrictive, however, for there have proved to be a great many places in the textile industry where the use of tubes is warranted. Seam detection at high cloth speed, liquid level indication without the use of floats, co-ordination of the speeds of succeeding motors in finishing ranges without the necessity for tension in the fabric between, photoelectric weft straightening, and hosiery machine drives are all examples of such equipments. The hosiery machine application is an example in which electronic drives have proved so successful that in the short time since the end of the war over 1,000 have been put in service and some 1,000 more are on the way.

Today's labor costs, after the tremendous increases the textile industry has experienced relative to other industries over the past eight years, justify expenditures for automatic electrical equipment. The opportunities for mills, machinery manufacturers, and the electrical industry to co-operate in the achievement of the ideal of more goods

Figure 1. Loom motor with built-in flywheel

for more people at lower cost in textiles are limitless.

F. D. Snyder: If a loom motor is designed for optimum performance by the proper combination of motor inertia and electrical characteristics for a specific application, then the addition of inertia by the use of a flywheel cannot result in gains. If a flywheel does result in gains then it can only mean that the motor was not designed for optimum performance. It is perfectly possible that one specific application needs more flywheel effect than another but if such is the case, in order to get optimum performance, the electrical characteristics must be changed at the same time.

Warp Knitting Machines

The fact remains that even with reliability of the present day "alnico" permanent-magnet type of plugging switch and the reliability of present day contactors, warp knitting machines equipped with such devices do occasionally reverse. It requires only one reversal to pay for many d-c braking controls.

Furthermore, d-c braking with line voltage and the proper rectifier produces a greater rate of deceleration than plugging at line voltage.

Axminster Carpet Loom Drives

The series type d-c variable speed drive as described in the paper is particularly well adapted to meet all the Axminster loom requirements. The various points brought out in the discussion can be answered by the following remarks.

1. The rate of acceleration can be adjusted in series variable type of drive by means of a simple reactor. However, this is not necessary if the drive is designed to accelerate smoothly and slowly in the first place.

2. The series variable drive has practically no droop in its speed torque characteristics. It does inherently drop the motor speed as load is applied but it slowly comes back to its original speed. This provides an excellent characteristic for the shockless acceleration of the needle motion. The characteristic is again adjustable by the use of a reactor.

3. The series fields of both the motor and the generator in this system is so low that the change in resistance value due to temperature change is very little. However, since both of these fields are in series with the motor armature and since most of the generated voltage is accounted for by motor counter electromotive force even a large change in resistance of the fields would mean little change in motor speed.

At the lower speeds where the generator field has a shunting resistor there might be a few per cent speed if the resistors are not designed properly but at the higher operating speeds the cold and hot speeds are very nearly the same.

4. The electronic drive still requires the same protection for the motor. Actually, a large number of properly screened d-c motors are being successfully operated in many carpet mills.

Electronic Devices

Demartini and the writer agree that the textile industry has many uses for electronic devices of all kinds. All that is necessary for electronic apparatus to be adopted for any given application is for this apparatus to prove that it is the most economical means to an end. Many applications have already proved economical, others will follow continuously as further research in their use continues.

Trends and Practices in Modern Industrial Power Distribution Systems

W. C. BLOOMQUIST
MEMBER AIEE

THE main purpose of this paper is to review present practices and trends of industrial power-distribution systems and to indicate, even though briefly in some cases, how they may be applied to new plants or in modernization and expansion of existing plants.

Many of our present tools were introduced in connection with the war effort when speed, ease of installation, reliability, and ease of operation and safety to personnel were so important. Although cost was often of secondary importance in the war construction program, yet because of the introduction of sound engineering principles of power distribution and the use of standardized factory-assembled equipments the over-all cost of the electrical power distribution system was low.

The main objectives for a power-distribution system are reliability, safety, low cost, flexibility, ease of operation and maintenance, and ease of installation. This paper shows how these features can be incorporated in a power system.

Present day practices and trends of the most important factors influencing a power system include load-center system of power distribution, higher main distribution voltages (4,160 or 13,800 volts) grounded system operation, protective devices of adequate interrupting capacity, and the use of metal-enclosed unit-type equipment.

Selection of Proper Voltage

System voltages can generally be conveniently divided into the following classes:

1. Utilization, generally below 600 volts.
2. Main distribution or generation, usually 2.4 to 13.8 kv.

In discussing the selection of system voltage, it will be well to first differentiate between the voltage rating of utilization equipment and generation or distribution equipment. The nominal system voltage corresponding to these is given in Table I and whenever the system voltage level is referred to, it is the nominal system voltage that is implied.

The selection of system voltages should be on the basis of availability of equipment and over-all economic considerations which are influenced by the plant electrical capacity and the cost of component parts of the power system including switching equipment, distribution channels, and transformers.

Figure 1. Selection of main distribution or generation voltage in terms of plant electrical capacity

Use of 460-Volt System for Low-Voltage Utilization Equipment

Although a 575-volt system is slightly more economical than a 460-volt system, the latter is by far the most common, due to the greater availability of utilization equipment. There are very few new 575- or 230-volt systems except as an extension of an existing system and then mainly in the interest of interchangeability of utilization equipment.

4,160-Volt Versus 13,800-Volt Systems

There is a definite trend towards the selection of 4,160 or 13,800 volts for main plant distribution. The use of 2,400 volts for main power distribution is decreasing, primarily because of cost and engineering limitations associated with expansion. Figure 1 is a guide to the selection of the main plant distribution or generation voltage for new plants and shows also the extent to which existing plants can be reasonably expanded.

Based on the installed cost of all components comprising the distribution system, a 4,160-volt system is generally more economical than a 13,800-volt system for plants up to about 10,000 kva. For plants in the range of 10,000 to 20,000-kva capacity, the two are comparable and above 20,000-kva capacity, a 13,800-volt system is usually the logical selection.

If past experience is any guide to future expansion, it would be well to allow for ample electrical growth in selecting the

Paper 48-118, recommended by the AIEE industrial power systems committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 2, 1948; made available for printing February 24, 1948.

Figure 2 (left). Cost of motors, control, and power system versus motor horsepower rating

Figure 4. Load-center method of power distribution

main voltage level and system arrangement.

440-Volt Versus 2,300- and 4,000-Volt Motors

Many plants use a large number of induction and synchronous motors in the 50 to 200 horsepower class. Since motors of this rating are available at 2,300 volts, it leads to the desire to select as many motors as possible for operation directly from a 2,400-volt main distribution system on the assumption that such an arrangement results in the lowest over-all system cost. Also, since 2,300-volt motors cost less than 4,000-volt motors, it has been assumed that a 2,400-volt distribution system costs less than a 4,160-volt system.

An examination of many cases showed that these assumptions are not true.

The results of these studies are included in Figure 2 and show that motors rated 200 horsepower or less should be operated on a 460-volt system and that a 4,160-volt power distribution system is more economical than a 2,400-volt system where large motors are operated directly at the main distribution voltage. Although these data pertain specifically to induction motors, they are also generally true for synchronous motors.

Where a 2,400-Volt System Is Applicable

A 2,400-volt system is applicable where there are large and concentrated motor loads served by step-down transformers from a 13.8-kv main distribution system. In this case, a 2,400-volt system rather than a 4,160-volt system is preferred. This choice is based on the relative costs of motors and control only and, as was shown previously, 2,300-volt equipment costs less than 4,000-volt equipment. Here the cost of the distribution system is not a factor, since the cost of transformation to 2,400 or 4,160 volts is practically the same.

Load Center System of Power Distribution

Prior to about 1941, there had been no major advance in power-distribution systems for industrial plants except for the introduction of metalclad switchgear and Askarel-filled transformers. Power systems were individually studied, and in most cases without proper evaluation of all components, and there was very little attempt to study basic patterns.

About 1941 a new approach was taken in studying industrial power systems, with particular reference to manufacturing

plants, and resulted in the load-center principle of distribution, which is now the accepted method of power distribution. Although the load-center principle applies to power distribution at all voltage classes, the following comments are directed mainly to low-voltage utilization services. There are two fundamentals associated with the load-center principle of distribution. These are:

1. Power is distributed at high voltage (up to 15 kv) to the center of the load. There it is stepped down to utilization voltage (600 volts or less) and distributed to the load by short, low-voltage feeders.

2. Where the total load exceeds about 500 to 1,500 kva, several unit substations are used rather than a single large substation. Each substation is located near the center of its load area.

The old method, which is referred to here only in the way of contrast consists of a large substation in which large blocks of power are transformed from high voltage to low voltage in one area and then the power distributed to the load areas by long, heavy-conductor feeders as shown in Figure 3.

Figure 4 shows the load-center method of power distribution for this same plant. In comparing the over-all economics of the load-center and the old method of power distribution, the only true comparison is on an installed basis and including all components, such as the primary switchgear, primary cable, transformers, low-voltage switchgear, and low-voltage cable. Unless all of these are properly evaluated, erroneous comparisons will result.

The optimum size of substation, considering all of the foregoing variables and contradictory trends, is shown in Figure 5. It should be noted that the optimum size of substation for 460-volt systems ranges from 500 to 1,500 kva, which is smaller than was generally considered economical previously. Although these data are based on a load density of 10-volt-amperes per square foot of plant floor area, the optimum size substation for other load densities ranging from 3 to 30-volt-amperes per square foot still come within this same general range. These data also apply to 575-volt systems. The load-center system is applicable to all sizes of plants where a transformation of voltage is required.

The following is a summary of the advantages of the load-center method of power distribution when using load-center unit substations (described later):

1. Low installed cost of the entire power-distribution system.

2. Ease of installation.

3. Adaptable to future expansion or modernization or expansion of existing plants. Unit substations may be considered as building blocks to be added as the load increases. This avoids the investment of extra capital in substations larger than necessary based on the anticipation of future increase in load.

4. Excellent voltage regulation because of short low-voltage feeders.

Table I

Utilization-Equipment Voltage Rating	Generator or Transformer No-Load Voltage Rating		Nominal System Voltage Class
220 or 230	240	.....	230
440 or 460	480	.....	460
550	600	.....	575
2,300	2,400	.....	2,400
4,000	4,160	.....	4,160
6,600	6,900	.....	6,900
13,200	13,200 to 14,400	.....	13,800

Figure 8. Outdoor stainless steel grounding resistor connected to neutral of a power transformer

Figure 9. Per cent system capacity released by power-factor improvement and the economical limits of obtaining additional electrical capacity by capacitors

If the load power factor of a substation is improved from 70 to 95 per cent, the system capacity released is 28.5 per cent; that is, the system can carry 28.5 per cent more load (at 70 per cent power factor) without exceeding the net kilovolt-amperes before the power factor was improved

This curve also shows that it is more economical to obtain this amount of system capacity by power-factor improvement with capacitors than purchasing additional substation and distribution facilities for all S/C values above 1.7 (obtained by interpolation)

5. Simplified engineering.
6. High salvage value.

Circuit Arrangements for Low-Voltage Systems

The over-all electric service reliability of most plants is excellent, yet management of some industries, and usually the large plants, is becoming actively interested in improving even the present excellent record.

Some of the reasons which have influenced management in this direction are as follows.

1. In some industries production workers are paid for a full day if sent home due to circumstances beyond their control.
2. Excessive overtime pay for maintenance or repair work.

There are cases where both of these have influenced the circuit arrangement for greater service reliability.

The reliability of a power system is dependent upon proper maintenance, the use of high quality equipment, and the circuit arrangement. Assuming proper maintenance and high quality equipment, the circuit arrangement greatly influences the potential reliability of the system and is the principal factor over which control can be exercised in the distribution layout.

The types of low-voltage distribution systems applicable to most industrial power systems are the radial and the secondary-selective arrangement, although there are other arrangements.

The radial system, Figure 6a, characterized by a single primary channel and substation, is suitable for general service where a power outage is not especially detrimental. The merits of the radial system are low cost and simplicity. This is the most common power-distribution system and practically the only one in small plants.

The secondary-selective system, Figure 6b and 6c, is especially suitable for continuous process loads, boiler house auxiliary supply, and whenever the service reliability and operating flexibility require more than that offered by a straight radial system. Basically, it consists of two independent radial systems but interconnected on the low-voltage bus through a normally-open tie circuit breaker.

It should be noted that with the secondary-selective arrangement, service reliability is the result of the system arrangement in contrast with some methods where service reliability is dependent upon the reliability of the type of equipment.

Some of the advantages of this arrangement are:

1. Duplication of supply to the low-voltage bus, thus providing continuous service for the entire load area. The primary circuits are usually physically separated throughout their entire length, making it impossible that a fault on one circuit will be transferred to the other circuit.
2. Retains the simplicity of the radial distribution system. No special relaying is required.
3. All transfer switching is performed by full-capacity air circuit breakers, thus contributing to safety. Transfer switching can be accomplished automatically, if necessary, at very little extra cost.

Figure 10 (below left). Outdoor load-center unit substation with explosion-proof air circuit breaker units in a Mexican oil refinery

Figure 11. Double-ended, 1,500-kva load-center unit substation with Askarel-filled transformers supplying power to 460-volt services. (Secondary-selective arrangement as shown in Figure 6b and c

Figure 12 (left). Indoor load-center unit substation with dry-type transformer

Figure 14. Cabinetrol unit for motor control containing starters for boiler feed pumps, fans, and stokers

4. During normal operation, each substation shares in carrying the load, resulting in excellent voltage regulation and low system losses.

5. Well suited for separation of lighting and flicker-producing loads. Lighting and power can be supplied from one substation and the flicker-producing loads and power from the other substation. During normal operation the two busses are not in parallel so the flicker load will not affect the lighting.

The spot network arrangement, as shown in Figure 6*d*, is applicable where the highest degree of service reliability is necessary. However, very few industrials have adopted any of the network arrangements.

The following are representative relative costs, on an installed basis, of these various types of distribution arrangements for 460-volt service as applied to medium and large-size plants:

Radial—100 per cent (base comparison).

Secondary Selective—105 to 140 per cent, depending upon the reserve capacity of transformers.

Spot Network—115 to 150 per cent, depending upon the reserve capacity of transformers.

System Grounding

The subject of grounding industrial power systems has received considerable attention the past few years as evidenced by the numerous articles in engineering publications. Operators are beginning to appreciate the benefits of grounded system operation and the over-all trend is definitely to grounded operation in the 2.4- to 13.8-kv class (practically all new systems above 5 kv are grounded). A few of the low-voltage systems, that is, 600 volts and below, are also being grounded, but not to as great an extent as the higher voltage systems. Although past experience offers little guidance on grounding, nevertheless a review of some of the factors involved, such as voltage, safety, and cost, are interesting even though somewhat inconsistent.

Offhand it would be expected that operating voltage level would be a clue to grounding and also that the higher voltage systems would be grounded both for engineering and safety reasons, yet that does not appear to be true. For example, 115 and 120/208-volt systems such as house circuits, are grounded primarily for safety reasons, yet very few higher voltage systems such as 460, 2,400, and 6,900 volts were grounded in the older installations.

As far as cost is concerned, there is practically no difference between grounded and ungrounded systems up to 15 kv. It is only on main transmission circuits of 69 kv and higher where costs become an important factor and then in favor of the grounded system.

The most promising clue is found in the type of transformer or generator connection, ungrounded systems are usually associated with delta-connected equipment and grounded systems with Y-connected equipment.

Since the trend is towards grounded system operation, what are the reasons for this? The following are briefly the advantages of grounded system operation and although applicable primarily to the main power-distribution systems, they apply generally to low-voltage systems also:

1. Automatic and selective indication of ground faults in feeder circuits.

2. Greater safety to personnel.

3. Reduction of overvoltages.

4. Better over-all protection to equipment, especially generators, transformers, and motors protected with differential-type relays.

Since many plants still operate with an ungrounded system, it may be well to review that type of system operation. The main and about the only argument in favor of an ungrounded system is that a grounded circuit can remain in service until it is convenient to shut down the

Figure 13. Installation of complete load-center unit substation and cabinetrol unit substation for motor control in plant of western lumber mill

Figure 15. Installation of 2—400-kw 250-volt 2-wire d-c sealed-ignitron mercury-arc rectifier unit substations with Askarel-filled rectifier transformers

Rectifier - cubicle door open showing mounting of rectifier tubes

Figure 18. Metal-clad switchgear serving main 2,600-volt boiler house auxiliaries in a southwestern oil refinery

plant. The main disadvantages are the difficulty and cost of locating grounds.

Since the main reason in favor of an ungrounded system centers around continuity of service, that should be examined closely. Service continuity is very important for some industries; they will accept the change of trip-outs due to multiple grounds or damage to equipment due to overvoltage in the interest of maintaining service until a shutdown can be planned. However, there are very few industries in that category; most plants can tolerate a short shutdown and there are always nonessential services which can be temporarily de-energized to repair a faulted circuit.

In most plants it is the total down time which is important and, since ground faults are quickly located on a grounded system due to automatic and selective relaying, the down time is usually less than for an ungrounded system. This has been demonstrated in plants which have changed to grounded system operation and, significantly, it is rare to find a plant changing back to ungrounded system operation.

The magnitude of ground fault currents in the main distribution system is purposely limited to rather low values; generally in the range of 500 to 2,000 amperes or a value consistent with proper relaying operation. It is advantageous to limit the magnitude of the ground fault current to minimize damage to rotating machinery, cable, switchgear, or any other metallic parts in the ground path. Typical grounding equipments for industrial plants are shown in Figures 7 and 8. A discussion of the various grounding methods is beyond the scope of this paper.

Economic Advantages of Capacitors

Capacitors are a useful and economical tool which should have much more use in industrial plants. The principal reasons for their use are reduction of power costs and release of system capacity. There are other benefits, such as improvement in voltage level and reduction of system losses, but these may be considered as additional advantages.

The principal reason for using capacitors is the reduction of power costs when a power-factor clause or its equivalent is part of the rate structure. Actual plant reports show that capacitors usually pay for themselves in a period of six months to two years. This corresponds to a gross rate of return on the capacitor investment of 50 to 200 per cent!

Capacitors are an economical and quick way of releasing circuit capacity to take care of additional loads or reduce overloading. This factor is especially important now when capacitor shipments are short, generally from stock or up to 15 weeks for the types commonly used in industrial plants, as compared with much longer shipment for distribution equipment. The use of capacitors for this purpose was not too well understood or appreciated in the past and may account for the fact that they were not used more for this purpose. However, the war demonstrated the importance of capacitors and many of the war plants included capacitors in the power distribution system. Also, many of the existing plants found capacitors a quick and economical means of taking care of their increased load and in many cases was the only practical solution. Figure 9 shows the per cent system capacity released by power-factor improvement and the economical limits of obtaining additional electrical capacity by capacitors.

Liquid-Filled Versus Dry-Type Transformers

The two principal types of transformers used on industrial power systems are Askarel-filled and dry-type and each has its own applications.

Askarel is a synthetic liquid which is noninflammable and has been used in transformers for almost 20 years. Because Askarel is noninflammable the transformer can be located indoors without a surrounding protective vault, and it is because of this feature that Askarel-filled transformers have been so popular for indoor location.

Dry-type transformers have been avail-

Figure 22 (right). Installation of a 460-volt small rack, dust-tight capacitor equipment commonly used in industrial plants

able for many years in small sizes and for low-voltage service (for example in lightning circuits). It was only in the last few years that they became available in the larger sizes and higher-voltage ratings for power distribution service. Since there is often a choice between Askarel-filled and dry-type transformers for load-center unit substations located indoors, Table II will serve as a guide for the selection of the proper transformer.

A dry-type transformer weighs less than an Askarel-filled transformer and this may be a deciding factor when the substation is to be located on a balcony or rafter.

Safety

The most important single item contributing to the safety of operators and other personnel is the use of metal-enclosed equipment. Practically all of the equipment components of high- and low-voltage power systems are metal-enclosed in the interest of safety. Typical metal-enclosed equipments include switchgear, unit substations, motor starters, transformers, capacitors, and bus run. Cable circuits are usually in conduit or equivalent or have an interlocked armored covering.

Mechanical-key interlocking is often used in the interest of safety to prevent improper operation of manually-controlled switches.

Danger of electrical shock to personnel, and especially to machine operators, can be reduced by proper arrangement of the plant-protective grounding system. This protective grounding system pertains to proper grounding of motor frames, and so forth, and is not to be confused with a grounded power distribution system as described previously.

Only when sufficient attention is given to the over-all protective grounding requirements is there assurance of an adequate and safe grounding system. This applies equally well to ungrounded or grounded systems and to high- and low-voltage power systems.

The protective grounding systems should have a direct path to ground in order to avoid unintentional transfer of ground currents among various metallic parts of the building and piping system, and to avoid differences of voltage between exposed metallic parts which might constitute a hazard to personnel.

The main grounding system should be interconnected with grounding paths via cable sheaths and plant piping. The plant piping system should be bonded to the steel of the building structure. The low-voltage protective grounding system to motor and starter frames, busway, transformers, and switchgear should be interconnected with the main grounding system.

Table II

Installation Conditions	Type of Transformer
Clean, dry conditions, free from lightning	Dry-type or Askarel
Dirty locations, oil vapors, chemical vapors, metal dust	Askarel
Wet locations	Askarel
Direct exposure to lightning	Askarel
Installed directly over machine tools	Dry-type or Askarel

Types of Equipment in Use

The present trend in power equipment is towards the use of factory-assembled unit-type equipment completely wired and ready for installation.

One advantage from the user's standpoint is the lower over-all cost, but there are others which will be mentioned later. This lower cost is the direct result of standardization and repetitive manufacture of component parts and assemblies. Standardization is not just an overworked expression, it is the real backbone of industry. Standardization of equipment by manufacture is just as desirable as standardization in manufacturing; the objective in each case is the same—a lower unit cost.

There is always the possibility of sacrificing flexibility by standardization. That is true if the over-all equipment is standardized. Electrical manufacturers of factory engineered and assembled equipments have provided adequate flexibility by standardizing component parts, not the equipment, and using these as building-blocks to meet practically any requirement. Take, for example, the

Figure 23 (left). Installation of 4,160-volt outdoor capacitor equipments such as used in large plants

Figure 24. Flexible and simple means of mounting and suspending interlocked-armored cable

standardized load-center unit substations; they are available with several types of incoming line arrangements, in various primary and secondary voltages, dry-type or liquid-filled transformers, various circuit breaker ampere and interrupting ratings, and are applicable to various secondary-circuit arrangements.

Some of the advantages and features of standardized factory-assembled unit-type equipments are:

1. Lower first cost.
2. Lower installed cost, generally in the range of 15 to 30 per cent less than piecemeal components assembled on the job.
3. Ease of installation.
4. Safety. In general, equipments are totally metal-enclosed.
5. Flexibility. Additional switchgear units are easily added.
6. High salvage value.
7. Simplification of engineering.
8. Simplification in ordering.
9. Neat in appearance.
10. Desirable operating and maintenance features such as drawout-type circuit breakers in switchgear.

A-c and d-c unit substations are available with liquid-filled or dry-type transformers for indoor service and liquid-filled transformers for outdoor service. Generally, they are located indoors near their load in accordance with the load-center method of distribution in order to obtain the lowest over-all system cost. Some of these various types of factory-assembled equipments are shown in the following:

A-C Unit Substations. Figures 10, 11, and 12 are unit substations with ratings ranging from 100 to 2,000 kva and are available for the common primary and secondary voltage classes.

Motor-Control Unit Substations. (Figures 13 and 14.) These combine the functions of transformation and motor control in a convenient equipment and are available for various motor control functions. Where a suitable low-voltage power source is available the transformer is omitted.

D-C Unit Substations. (Figures 15 and 16.) The d-c unit substation fulfills essentially the same need for d-c power as the a-c unit substation does for a-c service. These substations include a primary breaker where necessary, transformer, sealed-ignitron mercury-arc rectifier, d-c switchgear, and the necessary auxiliary equipment. They are available in ratings of 75 to 500 kw for 250-volt service and 75 to 1,000 kw for 600-volt service.

Metal-Clad Switchgear. Figures 17 and 18 are installations of modern metal-clad switchgear (up to 15 kv) used for main power generation and distribution circuits. The power circuit breakers are removable.

Master Unit Substations. Figures 19 and 20 are substations used for transforming the voltage when the incoming supply and main plant distribution voltages are different. They are available in a wide range of voltage classes, kilovolt-ampere ratings, and incoming-line arrangements.

High Interrupting-Capacity Fused Motor Starters. Figure 21 is economical motor starters with current-limiting fuses, available for use on systems of high interrupting capacity. These motor starters can be used for systems with fault duties of 150,000 kva for 2,400-volt service and 250,000 kva for 4,160-volt service.

Capacitors. Figures 22 and 23 are typical illustrations of capacitor equipments for industrial use; the individual capacitor units are enclosed in a metal housing.

Interlocked-Armored Cable. Figure 24 shows a cable installation with interlocked-armored cable. The installed cost of interlocked-armored cable is only 50 to 75 per cent of the installed cost of a comparable quality cable in conduit. Although this cable is not applicable to all plant areas—depending upon the atmospheric conditions—it should be used whenever possible to realize minimum cost for the cable system. This type of cable is available, with various types of sheaths under the armor, for service voltages up to 15 kv.

Discussion

John S. Parsons (Westinghouse Electric Corporation, East Pittsburgh, Pa.): A paper such as this, which undertakes to give trends and practices, should be very careful not to give a misleading picture. Also, it should clearly differentiate between facts and the author's views and opinions on controversial phases of the subject.

In this paper many of the author's views on various phases of the subject are given as statements of facts. For example, the statement is made:

> "Based on the installed cost of all components comprising the distribution system, a 4,160-volt system is more economical than a 13,800-volt system for plants up to about 10,000 kva."

I have studied many cases where plants having about half that kva demand could be more economically supplied at 13,800 volts when all factors including losses were

evaluated. Also, I have found many cases where it was economical to supply much larger than 200 horsepower motors from a 460-volt system. When I say much larger, I mean motors of more than twice that size.

I note that the author would use the secondary-selective radial system where service continuity and flexibility are required greater than that provided by a simple radial system. In my opinion the primary-selective secondary network system will provide much greater service continuity and flexibility than the secondary-selective radial system and at very little increase in cost.

The author makes the statement "very few industrials have adopted any of the network arrangements." The facts are as follows: The first industrial secondary network system was installed in 1936, and a few more up to 1941. However, from the beginning of 1942 to date, more than 80 industrial secondary network system installations have been made, and a very substantial number of them have been purchased and installed since the war. The majority of these industrial network installations have been of the primary-selective secondary network system, a type not mentioned by the author. To me these facts indicate some trend toward the use of the various forms of industrial secondary network systems, and in my opinion, it is a trend which will increase in the future.

Central Utility Power Service Versus Local Plant Generation in Industry

A. H. FRAMPTON
FELLOW AIEE

ADEQUATE, secure, and economical electric power service is a vital part of our present-day economy. The solution to the problem of selecting this service, in many of the varied forms of industrial and commercial establishment, normally is found in the selection of central utility service, the supply of which generally has been entrusted to central electric utility companies which enjoy virtual monopolies in their respective territories.

However, further investigation of the problem of power service oftentimes is indicated in those specialized, and usually larger, industries wherein the supply of steam, at various pressures and in substantial quantities, is one of the basic factors of plant design, or wherein plant processes present opportunities for energy recovery that cannot be ignored. Such industries will include, among others, those engaged in the refining of petroleum products, in chemical processes, in paper production, ore reduction or refining. Certain forms of commercial establishment, such as hotels, larger office buildings and hospitals, may be included in the former category.

In these cases, economic and other arguments may be advanced in favour of an independent, local generating plant, co-ordinated with the steam demands of the industry or with its other energy recovery possibilities.

It is the object of the paper to present and discuss certain principles inherently involved in the study of such cases, and to indicate that the selection, design, and correlation of the various plant services requires a detailed knowledge of all the factors involved. It is concluded, that the correct solution will be reached only when these factors have been accurately weighed and placed in their proper perspective. Precedent may indicate the correct approach to the problems, but not always the correct solutions.

Specification for Power Service

Modern industry usually purchases its major apparatus and equipment on the basis of a specification which the apparatus or equipment is required to meet. The preparation of such a specification serves two useful purposes with which this discussion may be concerned. First, it clarifies the thinking of the purchaser regarding the nature, the limitations and the expected performance of the item to be purchased and second, it becomes a statement to the supplier as to the type of product he is expected to offer and to supply.

Electric power service, in the cases under discussion, is also a competitive adjunct of industry, to be supplied by the central electric utility, or from the independent local generating plant. It naturally follows that a specification, which provides a basis for the comparison of the competing power sources, would be of material assistance in selecting that service most suited to the needs of the enterprise at large. More particularly is this true when it is remembered that the power service may have an important bearing, in fact, in certain industries, may be a governing factor, in production costs.

Paper 48-119, recommended by the AIEE industrial power systems and power generation committees and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 30, 1948; made available for printing February 24, 1948.

A. H. Frampton is director of engineering, The Hydro-Electric Power Commission of Ontario, Toronto, Canada.

Such a specification might be summarized as follows:

Dependability. The power service should be dependable and in so far as practicable, free from interruptions that hamper plant production and independent of natural forces and other conflicting influences outside the control of the industry.

Quality. The service should be of such quality as to provide satisfactory voltage, frequency, and other electrical characteristics necessary to the maintenance of established production standards.

Convenience. The service should be convenient and should not require, without adequate compensations in other directions, the establishment of trained staff, purchasing practices and other plant procedure foreign to the major objectives of the industry.

Adaptability. The service should be adaptable to the varying needs of the industry in its cycles of expansion or contraction, and should not create undue delays at the one time nor, at other times, give rise to burdensome charges that must be met during periods of low production.

Economy. Last, but by no means least, the service should be economical, measured in terms of both the direct and the indirect costs, as these may be reflected into the plant production.

Scope of Discussion

It is not possible to discuss each of these specification headings in the detail of fact and figure, nor to present formulas which will provide solutions for the infinitely varied problems this subject presents.

Furthermore, it would be difficult, in one paper, to cover the full possibilities of power generation and energy recovery that exist in the different industrial establishments throughout the continent.

In this latter connection, three principal fields exist in which the possibilities of the production of electric power in an independent local plant are presented. The first occurs in those plants whose processes

make available by-product fuels that can be used for the generation of power directly. The second occurs when it is desirable to use waste heat for the generation of steam, and when the steam so generated leaves a surplus over process requirements sufficient to warrant its use in electrical generation.

These two cases do not occur with great frequency and, in general, are of a nature which make the comparison of the economics a fairly straightforward process. The remarks which follow, under the respective specification headings other than "Economy," will be equally applicable in considering the design and service requirements of such plants, but further discussion of their economic factors will be omitted.

The third field is the one towards which this discussion is mainly directed, being that field in which industrial plant processes include large and relatively constant demands for steam at moderate pressures. In these cases, there is presented the opportunity of generating steam at pressures and temperatures higher than required for process, passing it through a turbine to produce electric energy, and supplying it to the processes at the necessary conditions, as exhaust.

From the casual consideration only it frequently may be concluded that attractive economies are possible. More detailed and accurately weighed analysis may indicate that such economies are more than counterbalanced by factors difficult to evaluate in monetary terms.

This discussion, therefore, will treat with each of the specification headings in general terms, in an attempt to bring out various viewpoints, leaving it to those concerned with specific problems to attach to each item the value or the weight which, in the light of the surrounding circumstances, appears justifiable.

Dependability

An adequate and acceptable standard of service security to its customers is one of the first principles of the modern electric utility system. During the recent war period, and while the utility industry is recovering from the demands of war and struggling with the problems arising from an unprecedented postwar load growth, its standards of service necessarily have suffered, to some extent. Nevertheless, this is but a temporary period, and its problems will be overcome. Serious and prolonged interruption of utility power service is an event of such infrequent occurrence that, when it occurs, it forms the material of newspaper headlines. Reserve generating equipment, reserve transmission and other power distributing facilities, adequate maintenance and overhauling of equipment during off-peak periods ensure the protection of power supply against all but the extremes of natural forces which occur so infrequently as to be uneconomical to guard against.

It must be granted, therefore, that the utility system can maintain a dependability rating as high as required by all but certain specialized enterprises, for which extremely rigid specifications must be established. The degree to which this standard of dependability is made available in individual cases will depend, to some extent, on the nature of the immediate supply facilities, but, at the most, a premium rate would ensure such additional protection as duplicate line supply or supply from alternative sources.

It is true that an independent local plant can be arranged to provide equally dependable service but, nevertheless, it appears that this factor is often discounted in the desire to secure apparently greater economy. Single generating units, for instance, may establish excellent records of continuous service, but the threat of a major plant shutdown is always present and occasionally occurs.

Accurate comparison of the alternative possibilities in this particular is made only if the local plant provides the standby and other provisions necessary to a high-grade service factor or, conversely, if the economic comparison provides a due allowance for the loss of production contingent upon the hazards to continuous service inherent in such design of the local plant as may be finally selected.

Quality

Again, the modern utility system is designed and so operated and managed to provide to its customers a service having high quality electrical characteristics. Temporarily again, these standards have become difficult to maintain, but over the long-term period normal characteristics are established and maintained by automatic and other equipment which approaches perfection in its operating characteristics.

Frequency is controlled to a degree that permits most manufacturing operations to be timed electrically, even those of such exacting requirements as paper making, nylon production and various chemical reactions. Voltage variations beyond normally acceptable limits are occasioned usually only by infrequent equipment outages.

The independent local plant may meet equally acceptable standards, providing the proper controls and so forth, are incorporated in its design. However, in exacting cases, where, for example, severe load swings are created by such as welding equipment, voltage flicker, or frequency problems may be important, or their solution difficult, involving control equipment whose adjustment and maintenance require highly qualified personnel.

Again, in the ultimate comparison, the allowable credit under this heading should be given the utility service or, in the converse, recognition made of the degree of service contemplated from the local plant, a recognition which may not be easy to reduce to a simple monetary figure.

Convenience

Convenience in the electrical power service may be stated to be as important to modern industry as convenience in the supply of its raw materials and other components entering into its manufacturing operations. From this viewpoint, this factor in our specification, not withstanding its seeming minor importance, becomes not infrequently the one factor on which the final decision hinges.

If the industry, or commercial establishment numbers among its normal staff, trained mechanical and electrical personnel, and if its purchasing requirements already include coal or other fuel, and if other governing considerations discussed later are present, then the installation of an industrial power plant, independent of central station service, may be viewed in one light. If the reverse is true, and the installation of an independent plant requires the establishment or major augmenting of a power department, executive policy may dictate the foregoing of such economies as may be indicated, in the interest of the major effort of the industry.

The industrial power plant inevitably increases invested capital and brings with it personnel and supply problems, which are avoided by central station service. Modern industry specializes, and frequently is content to place its power supply in the hands of the specialists in this field.

Adaptability or Flexibility

Industrial markets are never static, and fluctuate, to a greater or lesser extent, with the general economic condition of the community. It is desirable, therefore, that production costs be capable of variation in suitable ratio to production output. To this end, the power service

should be capable of simple and convenient expansion as required, but should also be capable of equally simple and convenient contraction in its cost aspect, at least.

Under normal conditions, central utility service would appear to meet this specification in both particulars. Expansion of supply is often as simple as making a telephone call to the power department of the utility. Contraction may go a long way before being limited by basic minimum charges.

The local industrial plant has decidedly different aspects. Once designed and constructed, its future revision almost certainly will be difficult. Not only will the desirability of revision be dictated by the simple expansion or contraction of the industry, but also, as so frequently happens, by changes in plant processes which alter the relationship of the steam and power demands and thus upset the basic factors on which the original design was based. It must be granted, therefore, that the local plant is less readily expanded to meet increasing demands, and certainly cannot be contracted, if production requirements decrease, except to the extent of fuel and possibly labour savings. Furthermore, it is susceptible to being placed in a substantially less favourable position than originally contemplated with variations in the plant processes. The newer the industry, the more recent the production process developments, the less certain the markets and the greater the hazards that should be recognized in basing production operations entirely on an independent local plant.

Economy

The comparison of their relative overall annual costs is obviously the key factor in comparing central utility service with the local generating plant. Such a comparison has the value of concrete figures, but the establishment of correct figures is not simple and, in fact, may be surrounded with difficulties such that erroneous comparisons often are submitted in perfectly good faith.

On the surface, the comparison appears simple. Central utility plants consume on the order of one pound of coal per kilowatt-hour generated, a consumption which is effectively increased in the inverse ratio of the efficiency of the transmission and distribution system. On the other hand, the local "by-product" plant, operating as described, with the exhaust steam utilized as process heat, will consume probably not more than four-tenths of a pound of coal per kilowatt-hour generated, the loss in the condensing water of the heat of vaporization being avoided. It would appear, therefore, that as at least 60 per cent of the coal is saved, the local plant must be the most economical.

A correct approach to the problem recognizes the existence of two separate problems; first, the supply of the required process steam and, second, the coincident supply of the necessary electric power. The cost of supplying process steam would be established on the basis of the minimum plant arrangement required to provide steam at the process pressures and temperatures. The additional cost of the "by-product" electric power supply then would include all the additional costs, above the basic minimum, required to provide the power generating facilities.

These additional costs would include the added capital costs in the boiler plant for higher pressure and temperature equipment, the capital costs of power generating equipment, the value of additional space requirements, together with all additional operating, maintenance and fuel expenses. These capital costs naturally would be affected by the degree to which the previous specification factors are to be recognized in the plant design, in the form of standby boiler plant and turbine equipment, automatic protective and control features and the operating costs by the calibre of personnel required to operate and maintain the plant components.

The designer, undertaking the problem of establishing these respective costs, first is faced with the problem of establishing the plant demands. This will not be simple, even though the plant appears to be identical to an already operating counterpart. Furthermore, it will almost invariably be found that a suitable balance does not exist between the process heat and electric power demands. Under such circumstances, the ultimate efficiency will be unattainable and a compromise arrangement imposed upon the designer, by which the maximum anticipated steam demands can be met and also, at noncoincident intervals, the maximum electric load.

This compromise requires the selection between two undesirable alternatives. Either steam must be generated at intervals at the higher pressure and temperature and passed through reducing valves with consequent loss of its energy generating possibilities, or a condensing section added to the turbine, requiring peak electrical generation in a condensing cycle and, in addition, the continuous wastage of steam through the added section, in order to maintain satisfactory turbine temperatures.

The number of combinations open to the designer in such circumstances depends primarily on the designer's ability to select, in advance, those which appear to offer the greatest promise. At the best, the plant arrangement will be such that maximum efficiency is attained only under one selected condition and, at all other conditions, some sacrifice of the theoretically possible gains must be accepted.

The extent of these sacrifices again depends on the accuracy of the demand estimates. There may be cases in which the steam and power requirements are so well established that forecasts of the future demands can be made with unfailing accuracy. Unfortunately, however, in the great majority of cases, this cannot be true, as management adjusts the production pattern of the industry to meet the fluid conditions of competitive enterprise.

Even the factor of seasonal variations will act to upset previously well-laid plans. No matter how long weather records have been maintained, there always seems to come a time when the unprecedented happens, and with it an entirely new relationship between, say, steam for process heating, and electrical demands for pumping cooling water.

It is then that the plant arrangement, which appeared so favourable on paper, often presents to management a balance sheet vastly different from that anticipated, in which the estimated economies have been partially, and frequently entirely, eliminated. In this connection, the author is aware of at least one plant in which, for months each year, conspicuous clouds of steam, at process pressures, are blown to the atmosphere, being uneconomical to salvage even though each pound of steam carries with it a thousand or more British thermal units of heat from the fuel the designer was attempting to save. Presumably, countless other and similar situations exist elsewhere.

It may seem on the surface that when such conditions exist, they could be corrected. Often they can, and are, but, when the original installation is completed, it frequently is impossible to make the changes necessary to offset changing requirements without plant revisions that cannot be justified economically.

In addition to the factors of cost that depend primarily on the steam and power generating facilities, the economic comparison must take full cognizance of other cost items, sometimes less readily apparent. One, for example, is the space requirement of the generating plant.

When the industry is located in a restricted area, the available space obviously is most economically utilized for the main production processes. The intrinsic value of the actual ground area may be relatively low, but, as part of the productive plant area, particularly if it represents the possibilities for future expansion, its actual value may be many times higher. This must be reflected in the economic comparison.

Other factors appear in the plant auxiliaries. For example, the higher pressure installation required in the production of by-product power may necessitate a complete revision of the methods of returning condensate to the plant or, in the alternative, a much more extensive and more costly feed-water treatment. The operating staff, entirely competent to operate a medium pressure installation, may be a definite hazard in attempting to operate a 1,200-pounds per square inch plant, requiring replacement with more qualified and higher paid personnel.

Not the least important factor in establishing correctly the economic balance sheet will be the proper allocation of costs between the respective production departments. The annual costs of a simple boiler plant, operating solely to provide process steam, probably are readily subdivided in proportion to the respective departmental demands.

When by-product power generation is added, the correct subdivision of total costs may be less apparent. For example in such a case, the steam generated at the higher pressure and temperature will be used by the power plant itself for feed water heating or other auxiliaries, will be used by the turbine plant for by-product electric generation, and may be used by certain plant processes through reducing valves. The electric-power output will be used by the production departments, and maybe also by the power plant for the electric auxiliaries, perhaps also by the water pumping plant supplying condensing cooling water. The water pumped by the pumping plant also may be utilized in two or more different departments. It will be evident that, where such complications exist, careful analysis of the respective costs will be required, if the balance sheet is not to indicate substantial savings in one direction and overlook possible increases in cost in others.

In summary, therefore, the economic comparison of the competing sources will need to be made with a full appreciation of all the factors involved. It must recognize that one plant only can be built, and that that plant will be a compromise, attaining its full economic possibilities only under one operating condition. Future changes in that plant will be difficult, so that long-term advantages will be secured only to the extent that the long-term requirements have been accurately forecast.

All of its cost items, including those of providing service standards comparable to the utility supply, must be included or, in the alternative, due allowance made for the hazards accepted in designing for lower standards.

The allocation of these over-all costs must be made in such manner that evident savings do not mask hidden losses in other phases of production operations.

Joint Operation of Local Plant With Utility

It might be concluded from the above discussion that local plant generation seldom can be proved economical, or that its adoption is so fraught with difficulties that the economies inherent in by-product power generation should be forgotten, in the interests of playing safe. This, however, is not the author's thought.

It is intended primarily to discuss as many of the viewpoints involved as space permits, in the interests of a correct approach to the problems. In this connection, an alternative is frequently presented, which often merits serious consideration, namely, the joint operation of a local industrial plant with the system of the adjoining utility.

Perhaps the most obvious situation where joint operation may be of advantage is when the normal process steam requirements are insufficient to generate the full electrical demands in by-product turbines. In such cases, the independent local plant is forced to add condensing sections to its turbines, and to generate the additional electrical demands in a condensing cycle.

It may still be, that an apparently satisfactory economic comparison is derived by combining all electrical generating costs in one figure, but a more correct comparison might indicate that part of the savings effected by by-product generation are offset by the additional costs of the condensing generation. In other words, that the local plant can economically supply up to the amount of its noncondensing generation, but that the utility most economically supplies the balance.

In certain industries the reverse situation may obtain, in that the steam demands are more than sufficient to generate the electrical requirements. Here, an excellent opportunity is presented for cooperative effort. Noncondensing generating capacity may be installed to utilize the full steam demands, the surplus output being sold to the utility, in return for which the utility, as well as paying an equitable rate for energy purchased, provides to the industry such valuable service factors as standby capacity, voltage, and frequency control.

These latter items naturally are of value whenever parallel operation with the utility is established. Under suitable contractual arrangements, the local plant can avoid expensive additional installations for standby automatically receives the benefit of the voltage and frequency regulation provided in the utility system, and is protected, in large measure, against the vagaries of future changes in power demand created by plant expansion or process changes.

In conclusion, it should be stated that, in each case where the comparison of a local plant with central utility service is undertaken, a new set of conditions will be presented. There is no absolute scale against which any proposal can be checked, the final evaluation depending almost entirely on the ability of the engineer to determine the limiting factors, and on his judgment in presenting them in their correct relationship. Unless the designer is absolutely honest with himself, he may be in the position of having made an entirely wrong decision, one which will remain as a monument to his errors of judgment.

It seems desirable that for any new industrial project there should be a specification for the power supply at least as rigid as those for the major items of equipment. The minimum requirements of such a specification would include the factors set out and discussed above; in certain cases, others might be added to cover specialized requirements.

In considering the means by which a power service meeting this specification is to be provided, by-product power generation may prove attractive in those industries requiring large quantities of low- or medium-pressure process steam. The decision concerning the extent to which the savings inherent in this method of operation can be realized should be made only after the most careful investigation, if the apparent gains are not to prove illusory.

Joint operation with the utility company, in many cases, will permit full attainment of these inherent economies. At the same time, it will provide other advantages, not the least of which will be those intangible values difficult to reflect into a purely monetary comparison.

Discussion

S. E. Schultz (Bonneville Power Administration, Portland, Oreg.): Generally I have found it worthwhile to review Frampton's technical papers inasmuch as they are based on intimate operating experience. This paper is no exception.

The need for close co-operation between the industrial engineer and the central station engineer cannot be overemphasized in any endeavor wherein the comparative merits of central station power and local generation are considered. It is important that the industrial engineer bring his problems to the central station engineer as early as possible.

He should carefully weigh all of the intangible as well as the tangible factors involved and present recommendations to his management that fully take into account the obvious advantages of central station power. On the other hand, the central station engineer should not be overly zealous in presenting the case for central station power.

As Frampton points out, local generation at times may prove feasible in an industrial plant where a large amount of processing steam is required for manufacturing purposes. There have been other cases in the Northwest where other factors have served as an inducement for local generation. These include:

1. Availability of low-cost fuel, particularly in large lumber mills.
2. Where service over a single circuit transmission line may not supply sufficient reliability.
3. Where the industrial plant is located near a low-cost hydroelectric site.

With due regard to the advantages of central service, the Bonneville Power Administration in its dealings with large customers has not overlooked the possibility of mutual benefits from local generation. Such generation has served the purpose of meeting the emergency needs of an area, even to the extent of shutting down some of the industry's own operations and of providing energy during a critical period.

Induction and Dielectric Heating

G. W. SCOTT, Jr.
MEMBER AIEE

WHEN an electric current passes through a conductor, heat is generated according to the equation

$$H = kI^2Rt \qquad (1)$$

where

H = calories of heat
k = 0.239
I = current through conductor in amperes
R = resistance of conductor in ohms
t = time in seconds

This equation is the basic law governing such heating by an electric current, known as resistance heating. It provides a very convenient and simple means for heating electric conductors, for the most part metals, that have been used very extensively for scientific, domestic, and industrial purposes. Although resistance heating is in most instances more expensive than heating by coal, oil, or gas, the added cost is frequently compensated for by the added simplicity and efficiency inherent in this type of heating. Examples of the widespread use of resistance heating are electric toasters and coffee makers in the home, electric furnaces and electrically-heated press platens in industry, and a host of specialized uses in scientific work.

Despite the very great convenience of heating merely by making suitable connections to a source of electric power, resistance heating has certain limitations, a number of which can be overcome by other types of electric heating. Unless the object to be heated can be connected directly to the source of power, one must rely upon conduction and/or convection in order to transport the heat to the desired point. If this is the case, resistance heating offers only convenience over and above heating between steam heated press platens or in a convection oven. Frequently this factor is not sufficiently important to justify the higher cost of resistance heating for a particular heating application. Furthermore, if the object to be heated is a nonconductor, resistance heating is of no use whatsoever. Fortunately, however, there are forms of electric heating that present advantages over conduction and convection methods and that even permit the heating of electrical insulating materials at rates and to temperatures of industrial importance.

In order to present an advantage over conventional oven methods of heating in cases where the charge to be heated cannot be connected directly to the source of power, a special case of resistance heating known as radiant heating may be employed. Whenever a temperature differential exists between two bodies there is a direct transfer of energy by electromagnetic radiation from the body at higher temperature to the one at lower temperature in accordance with Stefan's law which states that

$$E = \sigma(T^4 - T_0^4) \qquad (2)$$

where

E = energy radiated in watts
σ = Stefan's constant = 5.7×10^{-12} watts centimeter^{-2} degrees^{-4}
T = temperature of radiating body in degrees absolute
T_0 = temperature of receiving body in degrees absolute

The energy thus transferred heats the receiving body.

It is apparent from equation 2 that the transfer of energy and, therefore, the rate of heating by this method vary as the fourth power of the temperature differential. This implies that the rate of radiant heating increases very markedly with the temperature of the source. If the source is the filament of a lamp heated by the resistance method to incandescence (2,500 degrees Fahrenheit) or an open coil heated to a bright red color (1,500 degrees Fahrenheit), conditions for the transfer of infrared energy to a body at room temperature are very favorable. Such infrared lamps and resistance coils are very widely used for radiant heating in industry. A particularly worth-while application both from the viewpoint of reduced costs and improved quality is the drying of paint on an automobile body by passing it through a radiant heating tunnel. The most significant feature of radiant heating is the speed with which it may be accomplished. Since the energy is transferred from the source to the object under treatment with the speed of light (3×10^{10} centimeter per second) and is absorbed instantaneously, it is unquestionably one of the most rapid means of heating available. However, it must not be overlooked that the radiated energy under very nearly all conditions is completely absorbed in the first few thousandths of an inch below the surface. Consequently, radiant heating is a surface phenomenon. If it is desired to heat below the surface layers by this method, conduction of the heat to these regions must be relied upon. Although this does not drastically increase the time element involved in radiantly heating a thick section of metal, it seriously limits this method for heating uniformly throughout the volume of a nonmetallic material. In order to accomplish these purposes successfully and economically, the two remaining forms of electric heating must be employed. Induction heating provides a means of heating metallic objects at speeds comparable to those possible with radiant heating as well as more uniformly than with the latter method, while dielectric heating provides the only means of heating nonmetallic materials uniformly at high speed.

If an electric conductor, preferably a magnetic material, is placed within the turns of a coil through which an alternating current is passing, the metal is

Paper 48-121, recommended by the AIEE electric heating committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21-25, 1948. Manuscript submitted January 30, 1948; made available for printing March 5, 1948.

G. W. Scott, Jr., is with the Armstrong Cork Company, Lancaster, Pa.

Figure 1. Schematic oscillator circuit for high-frequency heating

R_1–grid bias resistor, C_1–plate tank capacitor, L_1–plate tank inductor, C_2–plate blocking capacitor, L_2–radio frequency choke, C_3–grid tank capacitor, L_3–grid tank inductor, L_4–radio frequency choke

heated by magnetic induction, which effect is normally referred to as induction heating. The greater portion of the heating in all cases is due to the eddy currents induced in the metal in accordance with Lenz's law. Magnetic hysteresis accounts for a small part of the heating in magnetic materials such as iron and steel when below the Curie temperature. The heating caused by the eddy currents is simply resistance heating in accordance with equation 1. An approximate formula for the heat generated in a metal by induction indicating the variables involved is

$$p = \frac{H^2\sqrt{\rho\mu f}}{8\pi} \qquad (3)$$

where

P = heat generated
H = tangential component of magnetic flux at surface of charge
ρ = resistivity of charge
μ = magnetic permeability of charge
f = frequency of current

The depth of penetration of the eddy currents in the metal is determined by the frequency of the source of power; the higher the frequency the less the penetration. This phenomenon is known as "skin effect." Variation of frequency in relation to the geometry of the charge allows the uniformity of heating throughout the volume of the charge to be controlled. If certain nonconducting materials are placed between two electrodes across which an alternating voltage in excess of one megacycle is impressed, a heating of the material will take place by dielectric loss. In the presence of the high frequency alternating electric field, polar molecules within the nonconductor are continually reoriented with variations in the electric field. By this behavior energy is dissipated as heat and an effective current in phase with the applied voltage may be considered to flow between the plates. The heating effect of such a current is governed by equation 1, the resistance term for which is the effective series or parallel resistance of this imperfect capacitor formed by the electrodes and the material to be heated. The heat generated between plane parallel electrodes in dielectric heating is governed by the equation

$$W = 5/9k \tan \delta f(E/d)^2 \times 10^{-12} \qquad (4)$$

where

W = heat in watts per cubic centimeter
k = dielectric constant of charge
$\tan \delta$ = dissipation factor of charge
f = frequency of power source in cycles per second
(E/d) = voltage gradient between electrodes in volts per centimeter

Induction and dielectric heating have in recent years been put to some very unusual and worthwhile industrial uses. It is felt that these unique forms of electric heating, can play a very important role in the program of industrialization now going on in Mexico, particularly in view of the additional electric power that is anticipated in that country. For this reason the remainder of the paper will be devoted to a detailed treatment of the theory and practice of induction and dielectric heating. Already the relationship of these methods to the other forms of electric heating has been illustrated.

Equipment

Induction and dielectric heating are both a-c effects. There, however, the similarity ends. Even in the matter of frequency there is considerable disparity between the two forms of heating. Induction heating is possible from 60 cycles upward to a few megacycles where lack of penetration makes it impractical, whereas dielectric heating becomes appreciable at about one megacycle and is improved with progressively increased frequency until tuning difficulties, standing wave effects, or availability of power render it ineffective.

Up to 9,600 cycles rotary generating equipment is satisfactory and available for induction heating. From this point to approximately 500 kc, spark gap oscillators may be employed. Above 500 kc it is necessary to employ a vacuum tube oscillator for both induction and dielectric heating. Such oscillators are readily available from United States manufacturers with output power up to 125 kw. This equipment is quite similar to that employed in radio broadcasting so that the radio frequency heating industry has benefited considerably from equipment development work done during the last two decades in the former field. The cost of this equipment will be analyzed later.

A simplified circuit diagram of an oscillator for radio frequency heating is shown in Figure 1. For both induction and dielectric heating, a common requirement is that the load to be heated be tuned to approximately resonance with the output of the oscillator so that power may be most efficiently absorbed from the latter. Figure 2 *A* shows a representative load tuning circuit for induction heating employing a series resonant circuit while Figure 2 *B* shows the same for a dielectric heating application utilizing a parallel resonant circuit. In either induction or dielectric heating, the charge to be heated may be placed in the proper component of the oscillator resonant circuit. However, this is not always as satisfactory as a separate tuned load circuit because of resulting instability in oscillator performance in the former instance.

Induction Heating

Induction heating is a very old phenomenon which was probably first seri-

Figure 2(B). Load tuning circuit for dielectric heating

L–tuning indicator, C–heating electrodes, D'–charge

ously encountered industrially for core losses in motors and transformers. Such losses in these instances were minimized by means of laminated core design, but have later been put to use for industrial heating.

A cylindrical metal charge D to be heated is shown in Figure 3 A within a coil L and placed symmetrically with respect to the axis of the coil. When an alternating current I flows through the coil L a magnetic field H parallel to the axis of the coil is produced as shown in Figures 3 A and 3 B. Once during each cycle the magnetic field H_1 or H_2 collapses and springs up in the opposite sense, inducing in the charge the eddy currents i_1 and i_2 as shown in Figure 3 B. Such currents heat the charge by the resistance effect in accordance with equation 1.

Furthermore energy is also dissipated in the charge from magnetic hysteresis, provided the magnetic permeability μ of the charge is sufficiently high. However, since $\mu = 1$ for all except ferromagnetic materials such as iron and steel and for all materials when above the Curie temperature, the heating by hysteresis is secondary in most instances to that by the induced eddy currents.

For convenience of representation the heat produced by hysteresis may be considered due to additional current flowing in a path parallel to the induced eddy currents. If this is the case, the equivalent circuit for the arrangement of Figure 3 is shown in Figure 4. The heating effect in the charge, of course, is proportional to i^2R.

Although a qualitative understanding of induction heating is simple to grasp, a solution of the differential equations representing the situation is involved and beyond the scope of this presentation. An approximate equation[1] for the energy dissipated per unit length of charge is

$$P = \frac{8\pi H_0^2}{\sigma} \cdot \frac{r}{d} \tag{5}$$

where

P = energy in watts per unit length
H_0 = impressed magnetic field in ampere turns per centimeter
σ = conductivity of charge in ohms per cubic centimeter
r = radius of charge in centimeters
d = depth of penetration of heating in centimeters

Of course the depth of penetration of heating is controlled by the skin effect and may be expressed as[1]

$$d = 2\pi \frac{1}{\sqrt{\mu \sigma f (10^{-9})}} \tag{6}$$

Figure 3(A). Induction heating work coil

Figure 3(B). Magnetic field around and eddy currents within an induction heating charge D

in which

d = penetration of heating in centimeters
μ = magnetic permeability of charge
σ = conductivity of charge in mhos per cubic centimeter
f = frequency of power source in cycles per second

Equation 5 is accurate for practical purposes when $r/d > 5$, that is when the penetration of the heating is no greater than 20 per cent of the distance from the surface to the center of the charge.

Although equations 5 and 6 show clearly the variables upon which the rate and control of induction heating depend, they are not useful for more than an approximate prediction of rate of temperature rise in a charge being heated. An important factor contributing to this fact is that the material variables σ and μ are both a function of temperature. In fact the permeability μ of magnetic materials drops abruptly to unity when the charge reaches the Curie temperature, causing a marked change in the slope of the temperature rise curve.

In Figure 5 are plotted power and temperature data taken during an induction heat treating cycle on a 20-millimeter armor piercing shot. It is observed that at the beginning of the cycle the rate of power absorption P increases as the temperature rises due in part to the decrease in conductivity of the metal charge at elevated temperatures. However, at the Curie temperature the magnetic permeability μ drops abruptly from a value of the order of 1,000 to 1 causing the considerable decrease in power absorption shown in curve P of Figure 5. This change in power absorption is reflected in the curve T for temperature rise in Figure 5.

Above the Curie temperature of the metal, the rate of temperature rise levels off. Practically, such a sharp change in material characteristics may be compensated for by retuning the load circuit, resulting in the temperature rise curve T_1 in Figure 5.

Up to this point the induction heating charge considered has been a cylinder placed symmetrically within the turns of a work coil. It should be emphasized that symmetry is not an inherent requirement of the method. A great variety of work coils of different shapes have been utilized to heat nonsymmetrical charges or to localize the heating in the charge as required. In the design of such coils it should be kept in mind that the efficiency of the energy transfer is determined in large part by the closeness of the inductive coupling between the charge and the work coil, that is, the factor M in Figure 4.

Although restriction of the penetration of heating by the skin effect to within a few thousandths of an inch of the surface in some instances is very desirable as in an application such as surface hardening, it is not adapted to the gross heat treating or melting of metals. It is apparent from equation 6 that the penetration d is inversely proportional to the square root of the frequency of the power source. Therefore, for a charge of specified cylindrical shape, there is a maximum frequency for

Figure 4. Equivalent circuit for induction-heating load

A—circuit of work coil, B—circuit of charge, M—mutual inductance between A and B

Figure 5. Power absorption and temperature rise during induction heating cycle

optimum over-all heating as expressed below.[3]

$$f = 7.9 \times \frac{\rho}{\mu r^2} \times 10^7 \qquad (7)$$

where

f = frequency in cycles per second
ρ = resistivity of charge in ohm-centimeters
μ = magnetic permeability of charge
r = radius of cylinder in centimeters

Quantitatively, equation 7 requires that the larger the cylinder to be heat treated, the lower the maximum allowable frequency.

Applications of Induction Heating

There are countless specific applications of induction heating in industry at the present time. These applications may be summarized under the following general headings:

1. Melting—flow of tinplate
2. Annealing
3. Heat treating
4. Surface hardening
5. Outgassing vacuum tubes
6. Soldering and brazing

The particular advantages of induction heating over conventional methods are:

1. Very great speed—power inputs up to 80 kw per square inch
2. Precisely controllable
3. Differential heating possible
4. Convenience
5. Contact not necessary—continuous process
6. Heat generated only in charge

The advantages from induction heating enumerated make possible certain of the applications listed just previously and result in cost reduction or quality improvement in the others. For instance induction heating is the only method by which the metallic elements of a vacuum tube may be elevated to a red heat for the purpose of outgassing while the tube is still attached to the vacuum pump. Such outgassing is essential to the long life of the vacuum tube.

The precise localization of heating made possible by work-coil design and the control of heat penetration from frequency variation greatly improves and speeds up many industrial soldering and brazing operations as well as makes possible many many others. The fact that the transfer of induction heat is essentially instantaneous and requires no direct contact with the charge makes it possible for certain of these brazing and soldering operations to be carried out continuously in production. Tin can be melted on black iron sheet at such a rate by induction heating to make possible the production of tin plate continuously at speeds as high as 1,000 feet per minute. This operation requires a frequency of 200 kc and an output of 1,200 kw.

The skin effect in induction heating makes it possible to surface-harden rapidly an object with irregular surface contours such as a gear. Furthermore, when the surface of a gear or other metal object has been raised to a red heat in a few seconds and the power immediately discontinued, the flow of heat inward produces an automatic self-quenching effect. In addition, the very great rates of heating and quenching possible with induction heating make possible the formation of metallurgical structures otherwise very difficult to attain.

In the face of the considerable advantage offered by induction heating it must be borne in mind that this method is inherently expensive and is normally not justified if other methods provide equivalent results. If the heating may be accomplished at 60 cycles, or normal industrial power frequency, the increased cost is only that of electric power over other available forms of power. However, if higher frequencies are demanded it is necessary to expend capital on special motor generator or oscillator equipment. In the latter case, the efficiency of utilization of the electric power is normally not greater than 50 per cent. More will be added regarding the cost factor after the discussion of dielectric heating.

Dielectric Heating

The first instance of dielectric heating probably took place in connection with the Leyden jar experiments conducted in Holland in the middle of the eighteenth century. The glass of the jar was heated by dielectric loss when the metal foils surrounding the jar were charged, producing an electric field in the glass. Since that time the phenomenon has occurred continually as a nuisance in the form of capacitor losses. Not until about ten years ago was dielectric heating established as a potential means of industrial heating.

In order to accomplish dielectric heating of a charge of normally insulating material such as wood, rubber, cork or glue, the charge must be placed between the plates of a capacitor C tuned with an inductance L as shown in Figure 6. The tuned load circuit is connected by a transmission line T to a power oscillator E operating at a frequency in excess of one megacycle. The electric field thus established across the capacitor causes the heating in the charge between the capacitor plates. The combination of C and D form an imperfect capacitor, and a statement of the theory of its behavior will determine the variables responsible for dielectric heating.

In an imperfect capacitor there is a component of current in phase with the applied voltage as well as the component 90 degrees out of phase, which is responsible for the dielectric heating. This in-phase current in a normally insulating or dielectric material is composed principally of two components, one due to ionic conduction, and the other due to dipole rotation. The latter is probably the dominating factor. Polar molecules within the material are continually reoriented with the alternating field, generating heat by friction. This effect in an imperfect capacitor may be attributed to resistance heating in an equivalent resistance placed either series or parallel with a pure capacitance. The alternate equivalent circuits of a charge to be heated dielectrically are shown in Figure 7 A and 7 B with the corresponding vector diagrams in Figures 8 A and 8 B.

Identical expressions for the rate of

Figure 8(B). Vector diagram for parallel equivalent circuit

dielectric heating may be derived from either Figure 7 *A* or 7 *B* provided it is remembered that

$$C_p = C_s \cos^2 \delta$$

For brevity the heating equation will be derived only for the parallel equivalent circuit. It is first necessary to evaluate the effective parallel resistance R_p which is of course responsible for the heating. From Figure 8 *B* it is apparent that

$$\cot \theta = \tan \delta = \frac{E/R_p}{\omega C_p E} = \frac{1}{\omega C_p R_p} \qquad (8)$$

and that

$$R_p = \frac{1}{\omega C_p \tan \delta}$$

in which $\tan \delta$ is defined as the dissipation factor of the charge being heated. Heating takes place in accordance with equation 1 so that

$$H_p = I_R^2 R_p = E^2/R_p = \omega C_p \tan \delta E^2 \qquad (9)$$

If equation 9 is evaluated for the specific case of heating a charge of uniform thickness between plane parallel electrodes, the result is

$$W = 5/9 k \tan \delta f (E/d)^2 \times 10^{-13} \qquad (10)$$

in which

W = heat generated in watts per cubic centimeter
k = dielectric constant of charge
$\tan \delta$ = dissipation factor of charge
f = frequency of power source in cycles per second
(E/d) = voltage gradient between electrodes in volts per centimeter

It is apparent from equation 10 that the rate of dielectric heating is directly proportional to the loss factor = $k \tan \delta$ of the charge being heated, the frequency of the applied voltage and the voltage gradient between the electrodes. Ideally it should be possible to increase the rate of heating indefinitely merely by increasing the magnitude of any one of these variables. There are in each instance, however, limiting practical considerations.

When the voltage applied to an electrode is increased, a value is reached at which a corona discharge takes place from it, or finally a disruptive arc. This limits the voltage available for dielectric heating to a maximum of approximately 15 kv, with a reliable, reproducible upper limit usually not exceeding 10 kv.

As the frequency of the voltage employed in dielectric heating is increased,[3] thereby making possible higher heating rates, the following difficulties are encountered.

1. Standing waves develop on the electrodes causing nonuniform heating.
2. Value of inductance required for tuning is decreased to an unachievable minimum causing difficulty in tuning.
3. Impedance of load is diminished causing difficulty in maintaining a high voltage gradient.
4. Losses in power oscillator tubes increase very rapidly.

Experience has shown that for large scale industrial dielectric heating the most useful frequency range is from 10 to 30 megacycles.

The remaining variable determining the rate of dielectric heating is the loss factor of the charge. This, however, is not an independent variable since for a given material both dielectric constant k and dissipation factor $\tan \delta$ are a function not only of frequency but of temperature as well. Figure 9[3] shows the variation of loss factor with frequency for materials *A* (cured neoprene with granulated cork as filler) and *B* (granulated cork with a cured organic binder) that are suited to industrial dielectric heating, and for a high frequency insulating material (Mycalex).

Although the changes in loss factor with frequency in Figure 9 are marked, they are not as significant as the changes with temperature indicated in Figures 10 and 11.[4] In Figure 10 are plotted both the dissipation factor $\tan \delta$ (curve *A*) and the power factor $\cos \theta$ (curve *B*) for granulated cork with an organic binder, while being heated from room temperature to approximately 220 degrees Fahrenheit during a curing cycle. It is to be observed that above 200 degrees Fahrenheit this material is very nearly equivalent to a metallic conductor. In Figure 11 curve *A* represents the variation of dielectric constant k with temperature and curve *B* the variation of loss factor $k \tan \delta$ with temperature for the same material. Figure 12[4] provides the corresponding curves of temperature rise and total current to electrodes as a function of time during a curing cycle of this material. During the heating cycle of Figures 11 and 12 the frequency was maintained constant at ten megacycles and the voltage gradient constant at 800 volts per inch. The change in the slope of the temperature versus time curve of Figure 12 must be attributed to variation of loss

Figure 9. Variation of loss factor ($k \tan \delta$) with frequency

Figure 10. Variation of power factor (cos θ) and dissipation factor (tan δ) with temperature

Figure 11. Variation of dielectric constant (k) and loss factor (k tan δ) with temperature

factor with temperature as has been shown to be the case in Figure 11. Therefore, equation 10 for rate of dielectric heating may be used only for qualitative predictions unless knowledge of the variation of the loss factor of the charge with temperature is available.

Great emphasis has been placed upon the fact that heat is generated uniformly throughout a volume in dielectric heating. It should be noted that this does not assure uniformity of temperature throughout the volume unless precautions are taken to avoid heat losses from the surface. In curve *A* of Figure 13 is a plot of temperature through the thickness of a volume at the end of a dielectric heating cycle where no precautions have been taken. A variation of approximately 20 per cent of the maximum temperature is to be noted even in a 6-inch thickness. Curve *B* of Figure 13 shows what may be accomplished by heating the electrodes by auxiliary means during the dielectric heating cycle to avoid heat losses at the surfaces in contact with the electrodes.

Another practical consideration in the use of either dielectric or induction heating oscillator equipment is radiation from it that may cause interference with other services such as radio, police, and military communications, or television. Unshielded heating electrodes and leads definitely radiate a signal as is clear from curve *A* in Figure 14 in which a maximum field strength of 376 microvolts per meter is measured at 1,500 feet from a 1.5-kw output dielectric heating unit. Experience has shown that the radiation pattern from such a unit is normally assymmetrical so that it is necessary to make a complete polar plot in order to determine the possibility of interfering radiation from a particular installation.

The problem of interference from induction and dielectric heating equipment has been recognized already in Canada and the United States. In the United States the Federal Communications Commission (FCC) has issued a definite set of rulings in the matter. The FCC has assigned the following channels to industrial heating 13.66 megacycles ± 0.05 percent, 27.32 megacycles ± 0.5 per cent and 40.98 megacycles ± 0.05 per cent. As an alternative any frequency may be employed provided the oscillator unit and load circuit are sufficiently well shielded that the field strength in any direction at one mile does not exceed ten microvolts per meter. The practicality of shielding is proved in curve *B* of Figure 14 illustrating that a maximum field strength at 1,500 feet of 376 microvolts per meter may be reduced to 42.3 microvolts per meter. At one mile the latter signal could not be detected. For either alternative some remedy must be made if industrial high-frequency heating interferes with other vital services.

Because of the difficulty of stabilizing the frequency of an oscillator and associated load circuit, particularly at high output power, to within ± 0.05 per cent or even ± 0.5 per cent, it is felt that the more practical approach to the problem of avoiding interference is shielding. The FCC rules are already in effect in the United States, and very likely there will eventually be international regulations in the matter. Therefore, it is recommended that this problem be considered in connection with the installation of induction and dielectric heating equipment in Mexico.

The cost of the equipment necessary for dielectric heating and high-frequency induction heating is relatively great. Therefore, it should not be considered in cases where equivalent results are possible by other means of heating. Despite the high capital investment required, however, the advantages of this type of heating are sufficient in many instances so that widespread use is being made of it in the United States at the present time.

In Figures 15*A* and 15*B* are plotted average costs for purchase and maintenance of such equipment. Figure 15*A* shows the initial capital investment required. Curve *A* in Figure 15*B* ,on the other hand, shows the total operating cost per hour of the equipment, which consists of curve *B* for power cost, curve *C* for tube replacement cost, curve *D* for depreciation on investment based on a 5-year life and 4,160 hours operation per year, and curve *E* for miscellaneous maintenance costs.

Applications of Dielectric Heating

From the preceding, it is evident that the outstanding advantages of dielectric heating are

1. Rapid heating cycles; materials conventionally requiring hours are heated in as many minutes.

2. Heat generated uniformly throughout volume, resulting in correspondingly uniform temperature provided certain precautions are taken.

Figure 12. Temperature rise and current to electrodes during dielectric heating cycle

Figure 13. Variation of temperature through the thickness of a charge heated dielectrically

Figure 14. Polar plot of radiation from dielectric heating equipment

A—equipment unshielded, *B*—equipment shielded

3. Precise control of heating possible.

4. Class of materials suited to dielectric heating (electrical and thermal insulators) most unsuited to conventional means of heating.

These advantages have resulted in dielectric heating becoming firmly established in the industries of plastic molding, plywood and furniture bonding, rubber processing, textile, and food.

One of the earliest applications of dielectric heating was in the bonding of plywood, especially that of high density. In order to set the glue line between the plies of a plywood board of appreciable thickness, it was necessary to hold the board between steam-heated press platens for times of the order of hours. With dielectric heating such boards may be bonded in a few minutes. This technique of setting glue or other adhesives has been carried over into the wooden furniture industry. Perhaps the most widespread use of dielectric heating, at least from the point of view of number of operating installations, is in the plastic molding industry. If plastic molding materials such as phenol and urea formaldehyde are preheated by dielectric means to approximately 250 degrees Fahrenheit prior to placing them in the forming molds, great advantages are realized. Not only is the molding time drastically reduced, but lighter molding processes may be employed and the quality of the product is improved. Because of the low thermal conductivity of rubber, the vulcanization of any rubber product other than a thin sheet is a time consuming process between steam-heated press platens. Natural rubber and most synthetic rubbers are heated very readily by dielectric loss so that by this means sections several inches thick are vulcanized in times of the order of a few minutes. Since the heat is generated uniformly throughout the volume of rubber, the vulcanization of cure effected is thereby more uniform and the quality of the product produced improved. The method has been applied to sponge or foam rubber as well as higher density material. So far as the textile industry is concerned, dielectric heating has been applied with very good success to drying and setting the twist in synthetic fibers such as rayon. There are several such large scale units in operation in the United States. In fact dielectric heating is likely the best method available for quickly and completely removing the final traces of water from materials. The drying of the drug penicillin on a mass production basis is a typical example.

Already dielectric heating is employed extensively in the food industry and it is anticipated to play an even more important role in the future. It provides a high speed and continuous method for sterilizing cereals and grains. Equipment is available, operating in the microwave range, that will heat ready to serve in 60 seconds a precooked frozen meal. As well as being convenient this method avoids considerable waste, particularly in railway dining cars and in airplanes.

One industry of importance in Mexico that is not benefited by dielectric heating is glass processing. The dielectric properties of glass, that is, dielectric constant k and dissipation factor $\tan \delta$ are of such an intermediate character that glass has a loss factor $k \tan \delta$ which is neither high enough to make it suited to industrial dielectric heating nor low enough to make a satisfactory high-frequency insulator.

Conclusion

Induction and dielectric heating, particularly the latter, have had a spectacular growth in the United States during the past ten years. At the present time there are approximately 500,000 kw of installed power for this type of heating in the United States, the equipment for which is valued at between $40,000,000 and $50,000,000. The volume of business in supplying this equipment is estimated to have doubled every four years for the past 30 years when induction heating was first used in industry. The annual dollar volume at present is approximately $8,000,000. At the present time the power in use for high frequency heating is far in excess of the power utilized for radio broadcasting in the United States.

Certainly induction and dielectric heating should play an important part in the industrialization of Mexico. The electric power is available, or will be soon, and many of the industries now in existence or planned for Mexico are those that can employ high-frequency heating profitably. Mexico will have the advantage that induction and dielectric heating equipment may be installed initially in new factories as they are built rather than be installed to replace, and therefore make obsolete, conventional heating equipment, as has frequently been the case in the United States. Although the capital investment for induction and dielectric heating equipment will be greater than that required for conventional heating equipment, the use of the former will certainly result in higher rates of production and improved quality with fewer rejects. A high level of production will allow product prices to be set lower than would otherwise be possible, which in turn will tend to improve the standard of living throughout Mexico.

Discussion

H. B. Osborn, Jr. and J. W. Williamson (Ohio Crankshaft Company, Cleveland, Ohio): This paper was presented for the purpose of outlining possible uses for induction and dielectric heating for the benefit of prospective users of this equipment. Unfortunately, however, the paper, as presented, is quite misleading and does not express the thinking and attitude of the manufacturers and users of induction and dielectric heating equipment.

Intended to interest people in the use of induction and dielectric heating, the various equations presented serve to mystify anyone but an electrical engineer. Let us not forget it is but rarely that an electrical engineer is involved in specifying processing equipment in a plant. Data on results and applications would have been more appropriate.

References to depths of penetration according to equations used are not in order in discussing skin effect. Skin effect to the user means the depth of hardness obtained when induction heating is applied for surface hardening. The equations refer to depth of penetration in which most of the electrical energy is concentrated in the case of a bar heated throughout. High frequency energy for surface hardening is used at power densities sufficient to minimize heat flow by conduction and leave the core cold. Only on through heating operations do such equations have any significance.

The skin effect in induction heating does make it possible to surface harden objects with irregular surface contours, such as gears. However, the implication that such a result can be obtained on all gears must be corrected. Due to the rapid heat flow by conduction, notwithstanding the short heating cycles and the pronounced skin effect of the high-frequency currents used, such processing must necessarily be limited to medium pitch and small diameter gears. In order to maintain high-power density per unit of surface area, high-powered high-frequency vacuum tube oscillators are required, the cost of which, to date, is prohibitive. However, in most cases, large gears are generally coarse pitch and 10,000-cycle equipment producing contour is used.

The statement is made that a gear or other metal object which has been raised to red heat in a few seconds can be automatically self-quenched by the action of the cold core. Again, an erroneous implication must be corrected. Obviously, this can only be obtained with materials of high hardenability, for example, high-alloy steels. Regardless of the shallowness of the depth of heating, a carbon steel cannot be hardened in production to complete martensite on the surface by the self-quenching technique. Since the majority of parts induction hardened are made of carbon steel, this point must not be overlooked.

The high cost of high-frequency equipment is generally admitted, but it should not be stated that such equipment should not be considered in cases where equivalent results are possible by other means of heating. Superior quality can be obtained with induction heating; further, there are also many jobs which cannot be done in any way except by induction heating. However, the majority of induction-heating installations are justified on a basis of cost of producing equivalent results due to the automatic features and high production which save on labor, reproducibility of results, and elimination of scrap.

The data shown in Figure 15*A* is incorrect, or at least improperly identified. It is possible that the author meant the cost of vacuum tube oscillator equipment, but of course this is not stated, and by implication the cost figures would apply to all high-frequency equipment. To illustrate, a complete 200-kw 3,000 cycle unit, tooled for processing of a part automatically, costs around $25,000. The same comments may apply to Figure 15*B* covering the operating costs. It is noted that Figures 15*A* and 15*B* are referred to in the section entitled Dielectric Heating. However, in various paragraphs before this reference, the author refers to induction-heating equipment as well, and in the paragraph directly preceding the reference, to the cost of such equipment.

The first subject considered in the paper is radiant heating, which, it is noted, heats only the outside of the piece. The author points out that, in contrast, induction heating is not confined entirely to the surface. If it is desired to take full advantage of this characteristic of induction heating for through heating, the frequency should not be too high. While these principles should be kept in mind, the conclusion that the maximum frequency should not exceed

$$f = 7.9\frac{\rho}{\mu r^2} \times 10^7$$

is not justified. For example, suppose a 2.0 inch diameter carbon steel load is to be heated to an average temperature of 2,100 degrees Fahrenheit. For an allowable 150 degrees Fahrenheit temperature differential, using a frequency of 3,000 cycles, the required heating time is 95 seconds. Other forms of heating would require a much greater heating time. Taking the resistivity of steel as 1.15×10^{-4} ohm centimeter, the frequency given by the above equation is 1,410 cycles. The value of 1.15×10^{-4} ohm centimeter corresponds to a temperature above that at which steel loses its magnetism. If a lower temperature were considered, μ would be much greater than one, and the frequency obtained would be very much less than 1,410 cycles.

Equation 3 correctly gives the rate of heat generation (abwatts/cm³) where H is expressed in oersteds. Converting to the units of equation 5,

$$H = 0.4\pi H_e$$

$$\rho = 10^9 \times \frac{1}{\sigma}$$

$$\sqrt{\rho\mu f} = \frac{1}{\sigma} \times \sqrt{10^9 \sigma \mu f} = \frac{10^9}{2\pi} \times \frac{1}{\sigma d}$$

Therefore, substituting into equation 3,

$$\frac{\text{Abwatts}}{C_m^3} = 10^7 \times \frac{H_e^2}{\sigma d}$$

Consequently, P in equation 5, representing the watts to the load per centimeter axial length, should be given by

$$P = 2\pi r \times \frac{H_e^2}{\sigma d}$$

The source of this error was in the reference quoted for equation 5. The authors of this book erroneously state that in going from just outside to just inside the load the magnetic intensity abruptly doubles. They therefore arrive at a value of P which is four times as great as it should be. Their derivation assumes a frequency such that the wave length of the radiation is negligible in relation to the radius of the piece heated. It might be that the derivation is corrected under the assumed conditions, but these conditions are not representative of ordinary induction heating practice. Frequencies of the order or 30,000 megacycles would be required for the assumed conditions to apply.

In the author's conclusion, he does state that the use of induction and dielectric heating equipment, though expensive, will result in higher rates of production and improved quality with fewer rejects. However, it is felt that such a statement is rather anticlimatic after what has gone before.

G. W. Scott, Jr.: It is the feeling of the author that it is rather presumptious on the part of the discussers to state so arbitrarily their opinion of the purpose of the paper in question. This paper was prepared for an audience of electrical engineers to give sufficient basic information so that an unbiased opinion might be formed of the applicability of induction and dielectric heating. Therefore the use of equations is quite appropriate and in the opinion of the author does much to counteract the influence of many loosely written papers appearing in trade journals prepared largely in an effort to promote the sale of induction and dielectric heating equipment. The term "skin effect" was used in electromagnetic theory long before the induction heating industry developed. Therefore, before an audience of electrical engineers it is considered appropriate to use the term thus.

The additional details provided by the discussers in the matter of surface hardening gears are interesting. In a short paper every point raised cannot be exhaustively treated.

The discussers object to the author's statement that high-frequency equipment should not be considered if equivalent results are possible by other means of heating. They point out that better quality can be achieved by induction heating or jobs done that can be accomplished in no other way.

A little thought indicates that in such cases equivalent results would not be possible by other means. Therefore this criticism appears groundless.

Figures 15*A* and 15*B* are admittedly somewhat ambiguously labeled. However from curve *C* in Figure 15*B* for tube replacement cost, it should be quite apparent to any electrical engineer, as indeed it was to the discussers, that vacuum tube oscillator equipment is implied. Elsewhere in the paper it is clearly stated upon what occasions such equipment must be employed.

The criticism of equation 5 should be passed along to Doctor Brown and the other authors of the book Radio Frequency Heating cited in reference 1.

A Brief Review of Switchgear and Circuit Breaker Practice in the United States

M. H. HOBBS
MEMBER AIEE

Although it obviously is impossible to cover all phases of current switchgear practice in the United States in a single paper except at great length, a general review is given here which will show the trend in several of the more important apparatus lines and their application to various industries. Statements regarding practices and designs have been made, so far as possible, to show those of representative systems and manufacturers. The figures, however, show only equipment produced by the company with which the writer is associated.

General

Primary circuit breakers and switchgear will be divided first into several basic classes, and the equipment applicable to each will be reviewed, covering the various locations, circuits, and industry applications in which it is American practice to use them. These classes are as follows:

1. Low voltage–up to 600 volts alternating current—750 volts direct current
2. Medium voltage–low or medium interrupting capacity 2,300 to 15,000 volts—25,000 to 500,000 kva.
3. Medium voltage–high interrupting capacity 15 kv to 34.5 kv—500,000 to 2,500,000 kva.
4. High voltage–46 kv to 287 kv—500,000 to 10,000,000 kva.

Low-Voltage Circuits

In the low-voltage field, as far as general application is concerned, there has been relatively little change in practice in the last few years. The applications include buildings, lighting, and power circuits of 120/208, 240, and 480 volts, industrial plant utilization circuits, and supply for lower capacity auxiliaries in power stations. Industrial plant and station auxiliary circuits are usually 480 volts, with a few plants retaining their former practice of 240 or occasionally 550 to 600 volts.

Except for certain industrial plant so-called "hazardous" locations where oil circuit breakers are supplied, the practice is uniformly to use air circuit breakers. The most important advances in recent years have been the replacement of semi-elliptical brush main contacts by silver line-to-line solid block type, and the elimination of the open arc by means of multiple-plate arc chutes. Carbon tipped arcing contacts have also been supplanted by arc-resisting metal alloys, such as copper tungsten.

The former and present standard mounting practice has been to mount the circuit breakers on insulating slabs of slate, asbestos, or similar material. The latest designs being brought out have the pole units mounted upon individual moulded bases which incorporate the terminal studs. These poles, two, three, or four as the case may be, together with the frame and mechanism, are then mounted upon a steel base or switchboard panel, providing a stronger assembly of lighter weight. Only the smaller circuit breakers are now operated manually and even these may be electrically operated for remote manual or automatic control. Figure 1 shows a late design circuit breaker.

Greater attention than in the past is being given to selective tripping of the low-voltage circuit breakers, particularly in larger industrial plants and for station auxiliary circuits. Although current transformers and relays are used on some of the heavier main supply circuit breakers and over-current and time-delay tripping characteristics in the majority of the circuit breakers are self-contained, a number of improvements have been made in these devices recently to obtain greater selectivity and reliability, in an effort to provide protection more nearly approaching that of relays with instrument transformers on high-voltage circuits. Of course there are limits as to what may be done in a complicated system.

For the structures in which low-voltage circuit breakers are enclosed, it has become almost universal practice to use metal-enclosed multiple-unit assemblies with circuit breakers which draw out for disconnecting and for maintenance and

Figure 1. Modern low-voltage circuit breaker of 25,000 amperes interrupting capacity at 600 volts, with steel base suitable for drawout mounting

Paper 48-122, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21-25, 1948. Manuscript submitted February 1, 1948; made available for printing March 9, 1948.

M. H. Hobbs is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 2. Metal enclosed low-voltage structure for drawout circuit breakers

Incoming circuits with heavy capacity breakers at the left, feeders at the right

inspection accessibility. These structures are factory assembled, tested and shipped in large groups, and the circuit breakers will interrupt their rated current when in their enclosures, due to the arc control obtained by the multiplate chutes mentioned previously. Stress is placed upon accessibility and safety, and interlocks prevent contact with circuit breakers unless they are withdrawn and thus disconnected. The busses are bare and mounted upon moulded insulating supports.

Figure 3. Magnetic blowout air circuit breaker removable element 150,000-kva 5-kv rating with baniers and left hand arc chute removed

Figure 2 shows an assembly of metal-enclosed units.

For 120/208 volts distribution in cities, the use of secondary network systems has become almost universal. The network is fed from transformers through low-voltage circuit breakers called network protectors. These trip automatically on reverse energy, indicating feeder trouble, and reclose if correct voltage conditions exist at the network transformer. In the larger cities the system is all underground with submersible transformers and network protectors located in manholes or vaults.

Medium-Voltage Circuits

In this class are included voltages of 2,300 to 15,000 volts and interrupting ratings of 25,000 to 500,000 kva. The field includes small power stations, municipal plants, steel mills, and other large and small industries, as well as the higher voltage (2,300 volts) auxiliary circuits in heavy power stations.

A material change has taken place in this field which was formerly served completely by small and medium capacity circuit breakers of the oil type. Although many oil circuit breakers are still used and will be for some time to come, the tendency is increasingly toward the magnetic blowout air circuit breaker, a complete line of which is now available with interrupting ratings from 50,000 to 500,000 kva.

The general construction of the oilless

Figure 4. Metal-clad switchgear structure for oil or magnetic blowout air circuit breakers for steel mill application 500,000-kva 7.5-kv rating

circuit breaker for 2.3 to 13.8-kv operation somewhat resembles that of the low-voltage device, with a hinged moving contact arm, primary, secondary, and arcing contacts, and multiple-plate arc chutes to confine and control the arc. This is brought about by the blowout coil through which the current passes, the magnetic force driving the arc into the slotted plates of the arc chute. Copper-tungsten arcing contacts are used and silver-to-silver main contacts. Each circuit breaker is mounted on its own wheeled truck which is withdrawn horizontally from its metal-clad housing, providing convenient disconnection and accessibility for inspection and maintenance. The circuit breakers are all solenoid operated. A typical 5-kv 150,000-kva circuit breaker unit with one barrier and one arc chute removed is shown in Figure 3.

Here again it is the practice to mount the circuit breakers in metal-clad switchgear, either vertical lift or horizontal drawout type. Relays, instruments, and control switches are mounted upon panels which either form the door through which the circuit breaker is removed, or are mounted on the opposite side. In any case, they are usually a part of the metal-clad structure, permitting the control wiring to be entirely self-contained except

Figure 5. Unit substation comprising transformer and outdoor metal-clad switchgear with magnetic air circuit breakers

Figure 6. Indoor power center with primary metal-clad switchgear unit at the left, air insulated transformer, and low-voltage metal-enclosed feeder units at the right

Figure 8. Side view of metal-enclosed cubicle with compressed air circuit breaker 1,500,000-kva 15-kv, showing disconnecting switches at the right and bus above

for the control supply cables. A steel mill installation with 500,000-kva circuit breakers for 6,900-volt service is shown in Figure 4.

Usually a single bus or sections of bus with ties between prove adequate. However, where a double bus is required, the metal-clad units are placed back to back and the circuit breakers are withdrawn from opposite sides of the structure. Shipping units comprise several units connected together and completely assembled.

Figure 7. Standardized unit substation with frame structure for high-voltage switching equipment, transformer and metal-clad switchgear for distribution feeders

As is also the case with the low-voltage equipment, both indoor and outdoor metal-clad switchgear units are available and many of both types have been installed in recent years. Their application is particularly suited to unit substations in the primary distribution systems, and a typical unit comprises a transformer fed from a high-voltage transmission line through a circuit breaker, fuse, or switch; and a metal-clad structure with a transformer circuit breaker and several feeders fed from a single bus. Voltage regulation is obtained usually by under-load tap changers on the transformer, rather than by individual feeder regulators. An example of an outdoor unit substation is pictured in Figure 5, and an indoor structure with dry-type transformer, a primary circuit breaker, and 440-volt feeder circuit breakers is shown in Figure 6.

For larger substations, additional feeders may be added, and also additional transformers, although the tendency is to use a larger number of unit substations of lower rating with fewer feeders in each. The primary network system of distribution has been used to a certain extent, al-

Figure 9. Installation of metal-tank oil circuit breakers for 230-kv 3,500,000-kva

thorgh the radial system seems more suitable in the majority of areas.

For the high-voltage circuits feeding the transformer, many systems use a steel frame structure upon which are mounted the busses, disconnecting switches and their connections, with the circuit breakers, transformers, instrument transformers, and lightning arresters located below. The most recent development in these structures is the trend toward standardization, which enables the building up of the larger assemblies from smaller basic units as extension of the station is required (Figure 7).

Although this standardization has not progressed to where manufacturers are justified in carrying basic units in stock, nor are the majority of operating companies following the plan, there is a definite tendency toward greater uniformity than in the past.

Medium-Voltage High Capacity

This is the class of circuit breakers and switchgear which has been used for the generator voltage circuits in large power stations and the more important substations in large cities. The voltage in the great percentage of stations is 13.8 kv, with interrupting ratings of 1,000,000, 1,500,000, and 2,500,000 kva.

Here again the tendency is toward oil-less circuit breakers, although in these ratings the type is compressed air rather than magnetic blowout. Many oil circuit breakers are still used, but installations of these are in general limited to additions to existing structures. Although the compressed air circuit breaker was introduced by American manufacturers only in 1940, the few intervening years have seen it become accepted almost universally for heavy power-station use.

The circuit breaker operating mechanism is also pneumatic, as compared to the electric solenoid mechanism used for oil circuit breakers, and its valves are interlocked to insure that adequate air pressure is available for the blast before tripping can take place.

Figure 11. Outdoor disconnecting switch with horn gap 46-kv rating, with high-pressure rotating blade contact

Switchgear structures for these circuit breakers are metal enclosed almost exclusively, but they differ from the lower capacity smaller structures in that the circuit-breaker unit is not the drawout type. Because of the circuit-breaker size, isolation is by means of disconnecting switches manually operated. All six switch poles on the two sides of the circuit breaker operate together from a single mechanism, which is interlocked to insure that the switches may be operated only when the circuit breaker is open. The doors giving access to the live circuit-breaker parts are also interlocked with the switches to permit their being opened only after the switches are open, and to insure that they shall be closed before the switches may be closed. Figure 8 is a cross section of a cubicle unit with a compressed air circuit breaker.

Another difference in construction between these heavy metal enclosures, called "cubicles," and the lower-capacity metal-clad switch gear is that metal barriers are used between phases to give complete phase isolation and insure against phase-to-phase faults in the structure. This is carried throughout the cubicle, from the circuit breaker to the outgoing or incoming circuit, and is usually followed on connection or bus runs to transformers or generators.

Instrument transformers are incorporated in the cubicles, the current transformers being the ring or bushing type, and mounted upon the disconnecting switch bushings. Potential transformers are the drawout type, preventing access to the fuses unless disconnected.

Although a very considerable amount of generator voltage switchgear is being installed in the United States, there is now somewhat of a trend toward its elimination except where required by distribution feeders connected directly to the generating station bus. The growing practice is for generating stations to feed bulk power over high-voltage transmission circuits and bus the circuits only at the high-voltage level. Thus, each generator and transformer, and perhaps even the line, become a unit with ties only on the high-voltage side of the transformer. As previously stated, where power is distributed at generator voltage from the bus, as is the case in many stations, switchgear at that voltage is obviously required.

A popular circuit arrangement, for medium and even high capacity stations, is the "synchronizing bus," whereby the

Figure 10 (left). Outdoor expulsion fuse 110 kv shown in partially open position

Tube swings down after blowing of fuse

Figure 12. Protective relay side of duplex switchboard

generators are tied together only through reactors to a bus which normally transfers relatively small amounts of power. This scheme reduces circuit breaker interrupting capacity materially, but power transfer and voltage regulation must be watched carefully. Many large industrial plants and steel mills have installed this bus arrangement. Metal enclosed cubicles and bus runs work out well with the synchronizing bus with the reactors as well included in the complete metal-enclosed structure.

There is a growing tendency to apply indoor compressed-air circuit breakers for 23-kv and 33-kv service, using indoor cubicles, and at least one outdoor-cubicle installation has been made. However, the majority of applications at these voltages, as well as many at 13.8 kv are served by outdoor oil circuit breakers of the frame mounting dead-tank oil type.

High Voltage 46 to 287 Kv

High voltage might be considered to include ratings lower than 46 kv, but the line here has been drawn at that voltage because the type of circuit breaker is almost exclusively outdoor at that voltage and above. Here the outdoor oil circuit breaker of the metal-tank type has been holding its own for many years against the inroads of other types, such as compressed air and "oil poor."

There are a limited number of installations of the compressed air and "oil poor" types in different parts of the country, some being experimental, but the great majority of circuit breakers being installed are the metal tank oil type. Improved interrupters have permitted the reduction in oil content by approximately 50 per cent in the past few years. Figure 9 is an installation view of 230 kv metal tank circuit breakers.

The demand for increased interrupting ratings has been much greater for high voltage than in the lower classes. The former American Standards Associations circuit-breaker tables list standard ratings only as high as 3,500,000 kva, and this only at the higher voltages. The tables as now revised list 3,500,000 kva at 69 kv, and 5,000,000 at 138 kv, 161 kv, and 230 kv. In addition, the bureau of reclamation has purchased for Grand Coulee power station, circuit breakers of 10,000,000 kva at 230 kv from two American manufacturers.

The interrupting time on high-voltage circuit breakers has been brought down in recent years until the standard for 230 and 161 kv circuit breakers is three cycles, measured from the time of energizing the trip coil. The 138-kv circuit breakers are five cycles, except the 5,000,000-kva rating which is three cycles. The 115-kv ratings are all five cycles and, for all voltages below this, the standard is eight cycles.

High-speed reclosing is becoming more common for the higher voltages, and 20 cycles has been made the industry standard for this feature. In order to obtain such speed, it is usual to supply pneumatic mechanisms. The electric solenoid, because of its greater simplicity and reduced maintenance, is still used widely on lower voltage circuit breakers and those not requiring rapid reclosing.

Ring-type current transformers for relaying and for instruments are mounted upon the bushings just below the mounting flanges, and in many cases potential taps on the bushings are provided for instrument and relay potential in place of instrument transformers.

Fuses

A large percentage of the fuses now used for higher voltage circuits are either the expulsion or the current limiting type. The latter has been applied for all voltages up to 15 kv and has been developed for special applications such as motor starting in which time-delay features are included, and for potential transformers where the current is unusually low.

The expulsion type has been developed both for indoor and outdoor use, and for outdoor applications ratings as high as 138 kv have been installed. After the fuse has blown, the tube swings down from its normal position to give a blown fuse indication. Such a fuse (115 kv) is shown in Figure 10.

Disconnecting Switches

The principal developments in indoor switches recently have been the standardization of insulator post dimensions, insulation levels, and strength classes, and the use of silver line contacts in place of flat copper. Modern switches are shown in the cubicle in Figure 8. In outdoor switches there is a growing tendency to use a high-pressure rotating-blade type of switch as pictured in Figure 11. The blade rotates completely out of contact before there is any movement about the blade hinge to the open position, resulting in very easy operation. The blade is counterbalanced by a spring in the casting which completely encloses the mechanism, and operation takes place from rotation of the intermediate insulator post. This type of switch may be mounted in any desired position.

Switchboards

All switchboards and control desks are now built of steel or other metal, providing stronger and lighter construction. Although many control desks are used, the trend is toward the duplex vertical panel arrangement, with spacing between front and rear panels wide enough for a working aisle. The instruments and control switches are mounted on the front or operating side, and the relays on the rear. It is usual to mount and wire all devices upon the panels in the factory and ship completely assembled. Figure 12 shows such a board.

Instruments, relays, and meters are quite generally the semiflush type which gives a very pleasing appearance, and relays are now furnished with built-in disconnecting and testing devices as standard.

Conclusion

Three general aims are evident in both the manufacture and application of switchgear and circuit breakers in the United States. First, a simplification in bus and circuit arrangement to provide the least complicated switching scheme to simplify operation and maintenance. Second, the purchase and installation of switchgear equipment as completely factory assembled as possible, to require the minimum field installation labor. Third, the elimination of oil in indoor circuit breakers, and greater use of magnetic blowout and compressed air types.

Discussion

R. L. Webb (Consolidated Edison Company of New York, Inc., New York, N. Y.): The author has done an excellent job of condensing a mass of information in his paper on Switchgear and Circuit Breaker Practice in the United States. He has covered the subject remarkably well in the short space allotted.

I would like to say a few words about some of our recent practices and experiences with switchgear in New York City.

In new generating station installations, auxiliary power will be supplied directly from the bus, or generator terminals, at 13.8 kv through small unit-substations, which consist of an air-cooled transformer and associated low-voltage air circuit breakers rated 600 volts. In one station, these substations are each rated 750 kva 3-phase 120/208 or 440 volts, and are located at strategic points around the station to be near the load they supply. The 440-volt stations for the larger motors are located only a few feet from the motors to avoid the cost of cables or busses. With this arrange-

ment, 440-volt motors and low-voltage switchgear were found to give the most economical design.

As Hobbs has said, use is being made of oilless circuit breakers wherever possible in the higher voltage systems. We have recently installed six distribution substations in the Queens district, each of which transforms from 27 kv to 4 kv. They supply four or six distribution feeders from each substation. The substations each consist of a 5,000-kva tap-changing-under-load transformer and a switchgear unit having automatic magnetic-air circuit breakers. The feeder circuit breakers have three single pole units mounted on a common framework, thereby forcing the outage of only one phase for a sustained line-to-ground fault on a 4-kv distribution feeder. The substations are completely automatic and are unattended.

Our experience with this type of switchgear and with air-blast circuit breakers at medium voltage—high capacity has been quite good. There have been no electrical failures and only minor mechanical and pneumatic difficulties. Our feelings toward oilless gear is perhaps best expressed by saying that we have recently placed orders for over $2,000,000 worth of switchgear for use at 4 kv, 13.8 kv, 27.6 kv, 69 kv and 138 kv; and all of it, with the exception of about $400,000 of 138-kv circuit breakers, will be magnetic air for 4 kv and air-blast at 13.8 kv, 27.6 kv and 69 kv.

We are now in the process of installing a 138-kv double circuit system around New York with direct connections, through transformers, to three existing generating stations and with provision for a fourth generating station connection, in the future. Since all 138-kv circuits in New York City are underground and elevated structures are undesirable, the exposed 138-kv circuits and busses at the stations and at two connected area substations have been designed for minimum height. The busses are made of $4^1/_2$-inch aluminum tubing and are supported on top of 138-kv insulators mounted on steel pipe posts. The structure presents a pleasing appearance with a minimum of structural steel supporting members in use.

S. E. Schultz (Bonneville Power Administration, Portland, Oreg.): Hobbs' paper presents a splendid summary, brief as it is, of the developments in circuit breaker practices. I am very happy to observe that it is now possible for the manufacturers to supply circuit breakers with a rupturing capacity on the order of 10,000,000 kva. This is a distinct advance over the previous circuit breakers rated at 3,500,000 kva. With circuit breakers of this larger rupturing capacity it is possible to achieve the maximum economy from the transmission systems that would have been handicapped if compelled to operate with smaller capacity circuit breakers. The development of the 10,000,000-kva circuit breaker is evidence of the benefits that can be derived by the cooperation of the manufacturer and the system operator, with each having a sympathetic understanding of the other's problems.

I think that it is timely to suggest that the manufacturers consider the building of a low-cost load break disconnecting switch for voltages as high as 230 kv. The need for such a switch on the Bonneville Power Administration transmission system is quite pressing, so much so that active steps, including the testing of such devices, have been undertaken with certain manufacturers.

H. J. Lingal (Westinghouse Electric Corporation, East Pittsburgh, Pa): The paper by Hobbs was solicited by the AIEE switchgear committee for the purpose of making information available to our Mexican associates on current practice in switchgear construction in the United States, and to indicate for their guidance the probable trend of switchgear design and construction as we foresee the future.

During the period when engineers from Mexico were studying designs and accumulating manufacturing information to begin production of electrical switchgear by Industria Electrica de Mexico, S.A., I had the opportunity to work very closely with them and urge the use of methods and designs developed in the United States without overrating on the expectation that lighter duty or tolerance of lower grade performance would permit use of lower rated apparatus.

At this time I should like to repeat a word of caution, not only to the Industria engineers but to all our Mexican friends, that there is danger in overapplying or in overrating apparatus on the assumption that money would be saved by taking some additional operating risks.

The application of switchgear beyond its proved rating may be completely satisfactory operating practice for the immediate time, but as the industry develops and its requirements become more severe, as they surely will in the future of Mexican power system operation, vast benefits will be derived from following what may appear now to be too rigid application practice. Almost all standards in the United States are higher and not lower than in the past, and operators have always been grateful for any safety factor which has been present in the equipment. The apparatus used by the author to illustrate the type of switchgear now operating successfully in the United States required many years to develop and prove, and he has chosen it carefully and well. We wish to commend the author on his selections and recommend them for the consideration of the growing electrical industry in Mexico.

M. H. Hobbs. The discussions of my paper by Webb, Schultz, and Lingal are very much appreciated. Although no controversial points have been raised, the following comments on these discussions seem pertinent.

As Schultz has stated, the development of the 10,000,000-kva circuit breaker is an outstanding example of co-operative effort between the manufacturers and large forward-looking users' organizations, such as that of Schultz and of the Bureau of Reclamation. It is only by this means that the development would have been possible.

He mentions the desirability of a low-cost load break disconnecting switch for voltages as high as 230 kv. It is understood that Schultz has reference to switches which are suitable not only to break load but to be used as fault interrupters for limited kilovolt-amperes in connection with isolated loads.

Although the need for such devices is apparent, their low cost and simplicity depend upon the minimum requirements being given. Where higher interrupting requirements, electrical closing, and automatic reclosing are necessary, the device again approaches a full scale circuit breaker, and the cost rises accordingly. As has been stated, several manufacturers are at present working on the problem.

Webb has given us a very complete picture of the practice in switchgear and circuit breakers followed by his company in New York. Of particular note is the trend toward oilless circuit breakers, culminating in the purchase of the 69-kv compressed air units, the first commercial installation of such circuit breakers for this voltage in the United States. This selection was made only after exhaustive studies of the offerings of American manufacturers.

The installation of 138-kv bus, and equipment referred to in his last paragraph, is outstanding and will undoubtedly appeal to many operating engineers.

The Grand Coulee Power Development

S. M. DENTON
ASSOCIATE AIEE

THE Bureau of Reclamation announced in 1903 that the soil in the Columbia Basin was suitable for irrigation and in 1911 further reported the soil to be high in fertility. The only source of irrigation, the Columbia River, was about 600 feet below the irrigable land, and there the matter rested until 1922 when General Goethals of Panama Canal fame stated that a plan for a dam, power plant, and pumping plant was sound. Support for the plan grew, and it was favorably commented upon by Secretary of Commerce Hoover and by President Coolidge.

On July 27, 1933, the Federal Emergency Administration of Public Works provided an initial allotment of $15,000,000 to begin construction, and an additional $20,000,000 was made available on June 21, 1935, under the Works Relief Program to continue construction. The Interior Department Appropriation Act of June 1936 provided $20,750,000 for the project. Subsequent appropriations allowed completion of the dam and an orderly power plant installation as well as investigations and surveys for the irrigation development.

The irrigation development will bring water to one of the largest bodies of undeveloped land in the United States. The proposed power installation when completed will exceed any power plant output of today.

Planning the Development

The Grand Coulee Dam and power plant, which is a part of the Columbia Basin Project, is located in the state of Washington about 90 miles west and north of Spokane and about 240 miles east of Seattle. The dam and power plant are in the Columbia River immediately downstream from the point where a great cleft was carved in the river canyon south wall centuries ago by the antediluvian waters. This cleft is known as the Grand Coulee.

The geologic history of the project area is interesting, but perhaps only a brief summary of the later developments that were responsible for the natural conditions to which the project was adapted are pertinent here.

During the period of the Pleistocene era when ice sheets spread over North America, an ice mass blocked the deep canyon of the Columbia River at this point. The river formed a huge lake and flowed over the rim of the canyon and started cutting a new channel at right angles to its former course. Thus, the Columbia River gouged a new canyon, the Grand Coulee, 50 miles long, from 500 to 1,000 feet deep, and from two to five miles wide. After thousands of years the ice obstruction melted away and the river returned to its original course, leaving the cleft cut by the overflow, high and dry.

The river canyon at this point provides an excellent power site. A natural site for a huge regulatory reservoir for irrigation supply is made by the addition of two dams in the Grand Coulee. The reservoir is about 27 miles long covering an area of approximately 28,000 acres with one dam about 90 feet high approximately two miles from the main dam, and one about 100 feet high near the town of Coulee City. It will store about 700,000 acre-feet of water at an elevation that will enable irrigation of 1,000,000 acres of arable lands by gravity flow. These lands are covered by a deep and rich blanket of soil that will be highly productive when irrigated.

The water supply for the regulatory reservoir will be taken from the Columbia River. The Grand Coulee dam will raise the water over 300 feet, but the additional lift of 270 to 365 feet of the huge flow required will necessitate pumping on an unprecedented scale. A pumping plant is being built adjacent to the upstream face of the dam along the left bank of the reservoir. The pumping plant building contemplates an ultimate installation of 12 pumps. Six pumping units are now being manufactured and are rated 1,600 cubic feet per second with 295-foot lift. Each pumping unit comprises a vertical-shaft centrifugal-pump direct-connected to a 65,000-horsepower motor which will operate at 200 revolutions per minute.

The cost of power from the Grand Coulee development will compare favorably with the cost at the most economical sites in North America. The low cost of power at this site makes the pumping of water for irrigation purposes economically feasible.

The Columbia River above Grand Coulee dam has a drainage area of approximately 79,000 square miles, and it has an average annual discharge of 80,000,000 acre-feet. The average river flow is just over 100,000 cubic feet per second at the Grand Coulee dam site.

Franklin D. Roosevelt Lake, which is the reservoir formed by the dam has a storage capacity of about 9,500,000 acre-feet of which 5,165,000 acre-feet is live storage. With a drawdown of 80 feet, a firm continuous power output of 925,000 kw can be maintained. This will be improved with the addition of upsteam storage and regulation such as the Hungry Horse development which is now under way.

Grand Coulee dam, which is approximately 4,200 feet long, is provided with 11 spillway gates each 28 feet high by 135 feet long, and has 60 $8^1/_2$-foot-diameter outlet conduits. Designs for flood flow were based upon a discharge of 1,000,000 cubic feet per second over the 1,650-foot-wide spillway. A power plant is located on each end of the dam. Pumping power

Paper 48-123, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 9, 1948; made available for printing March 9, 1948.

S. M. Denton is with the United States Bureau of Reclamation, Denver, Colo.

Figure 1. Map of the Columbia Basin Project

requirements can be met largely by utilizing off-peak power.

Basic Arrangement of Power Plant

The large flood flow and the unprecedented height of the overflow spillway dictated that the spillway be located in the midsection of the dam. The length of the spillway section allows insufficient space at either end of the dam for the entire power development. The power plant was accordingly divided into two sections, with one powerhouse on each side of the spillway section. The amount of power to be developed and the limited space available indicated that units of the largest practicable size should be used. One limiting feature was found to be the physical size of the turbine runner. It was deemed important that the turbine runner be of one piece construction in order to avoid a bolted connection and the hydraulic disturbances which such a connection would entail.

The powerhouses are located on the downstream toe of the dam which is the most economic, simple, and desirable arrangement. The best operating conditions and hydraulic efficiency resulted from this arrangement permitting the shortest possible penstocks. The fluctuation of more than 80 feet in the water surface of the tailrace complicated the designs for the powerhouse structure. The low setting of the turbines and the large tail water fluctuation necessitated heavy transverse walls to carry the water pressures. Generator and gallery floors were designed as girders transmitting the heavy water-pressure loads into transverse walls between units. These considerations resulted in the location of the generators 53 feet above the center line of the turbine scrollcase.

The power plant location on the toe of the dam provided a deck between the upstream generator room wall and the dam where the transformers were located. The generator voltage busses, the 230- and 115-kv lightning arresters, and a take-off structure for the transformer circuits are also located between the generator room and the dam. This arrangement eliminates a more expensive transformer supporting structure above the draft tubes, as is more commonly used. Towers for supporting the 230-kv transformer circuits are located on the roof of the powerhouse.

The main generator room is equipped with two 350-ton cranes for use in erecting and servicing the generating units. The heaviest parts require both cranes working in tandem with a lifting beam. The service bay is at the entrance end of the generator room and provides space and facilities for erecting the turbines, generators, and transformers, and also unloading and setting down space.

The governors, gauge and thermometer boards, unit control and power boards, and the entrances to the turbine pits are located in the governor gallery. This area has sufficient indication and control facilities to permit emergency operation of the units. Longitudinal galleries through the powerhouse substructure serve for piping control cables, generator voltage busses, and other equipment.

The control room for each powerhouse is located at the abutment end of the powerhouse. A terminal board room is located immediately below the control room and a cable spreading room is provided below the terminal board room. The cable spreading and cable terminal rooms are usually combined in smaller

power plants, but separate rooms are advantageous in plants of this magnitude.

The Grand Coulee left power plant building houses nine main generating units and two station-service generating units with all necessary controls, protective devices, handling and service equipment. Provision is also made for a future third station-service generating unit.

Generating Units

Turbines

Nine hydraulic turbines each rated 150,000-horsepower at 330-foot head and 120 revolutions per minute are installed in the left powerhouse. The right powerhouse will house nine turbines of similar rating. At 263-foot head, each turbine will develop 90,000 horsepower. The effective head under which the turbines will operate may vary from 263 to 355 feet.

The turbine runner is of the Francis type and is of 1-piece cast-steel construction. The turbine shaft is 44 inches in diameter and is provided with a 6-inch-diameter hole bored axially throughout its entire length to permit inspection of the metal in the interior of the shaft.

The turbine guide bearing is of the babbitt-lined, oil-lubricated type. Oil is circulated through the bearings by means of either of two motor-driven oil pumps. One oil pump is driven by a 3-phase a-c motor connected to the station-service system. The other pump is a standby pump driven by a d-c motor from the station battery and is arranged to start upon failure of the oil pressure.

The speed ring and scrollcase are of cast steel construction and divided into sections small enough to meet shipping limitations. Removable and renewable wearing rings are provided for close-running clearances between the runners and the stationary parts of the turbine. The servomotors have a combined capacity to supply the maximum force necessary to operate the turbine gates with a minimum oil pressure of 250 pounds per square inch and will move the turbine gates a full opening or closing stroke within a 4-second interval.

Many unusual problems confronted the engineers in connection with the design and installation of these turbines due to the fact that they are the largest hydraulic prime movers in existence. The treatment of a few of these unusual problems is described herewith.

Each turbine is provided with a double gland expansion joint to permit relative movement vertically as well as horizontally between the power plant and the dam to accommodate expected vertical movement at the toe of the dam due to the great pressures in this area with the reservoir filled. This joint has proved very satisfactory.

The size of the Grand Coulee turbines was determined by the limits of foundry practice and shipping clearances. The turbine runner measures 16 feet 8 inches in diameter, is 6 feet 8 inches in height, and weighs over 125,000 pounds.

The center line of the turbine distributor was set unusually low to accommodate a high specific speed turbine designed to operate at 120-foot head during initial operation and later to operate satisfactorily at the ultimate head of 330 feet. The low head arrangement was not used, however.

Extensive tests were made on the effect of size and shape of groove to receive round rubber gaskets for sealing the bolted flanged joints. These tests showed the best results were obtained when the area of the groove equaled the area of the rubber gasket. For all practical purposes, the rubber may be considered as incompressible.

Field tests show an over-all efficiency of the unit including generator losses, of 90 per cent. These turbines develop 165,000 horsepower at 330-foot head while discharging approximately 5,000 cubic feet of water per second. Two station-service turbines are also installed in the left powerhouse. Each of these turbines drives a 12,500-kva, 80-per cent power-factor generator and is rated 14,000 horsepower at 400 revolutions per minute.

Each turbine is supplied through a concrete and steel trashrack structure at the upstream face of the dam. A vertical gate operated by an oil-actuated hydraulic hoist is mounted at the upper end of each penstock and controls the water flow into the penstock. Each unit is supplied by an 18-foot welded-steel penstock with a reducing bend at the turbine connection.

Governors

The governors for the 150,000-horsepower turbines are of the oil-pressure, relay-valve actuator type with electrically driven speed-responsive elements. The speed-responsive elements are actuated by permanent-magnet generators connected to the upper ends of the generator shafts. The governors control the wicket gates by means of oil pressure applied to the servomotors and are adjustable to provide variable rates of operation from completely opening from closed position or closing from fully open position in four seconds minimum up to 12 seconds maximum. The speed responsive elements are sensitive to 0.01 per cent variations in turbine speed. The governors may be operated manually at the governor or

electrically by remote control from the main control board and include the following features:

1. A gate-limit control device.

2. A speed-level controlling-device with selsyn transmitter and receiver with micrometer adjustment.

3. Manual and automatic starting and shutdown.

4. A device for controlling the speed droop of the turbine. The amount of speed droop is adjustable from 0 to 5 per cent.

5. Speed indicators driven by a magneto-type generator located in the governor-drive-generator housing and geared to the governor-generator shaft.

6. Position indicators for indicating the position of the gate limit device and of the turbine gates.

7. Overspeed switch arranged to shut down the turbine and sound an alarm upon overspeed. The overspeed switch is adjustable to operate at any desired speed above 120 per cent of normal. The switch automatically resets at 115 per cent of normal speed.

8. Manual control of the turbine gates at the actuator by means of oil pressure from the governor oil-pressure system.

9. A combination automatic hand-control

and hand-operated air valve for controlling the operation of the generator brakes. The arrangement is such that the brakes cannot be applied automatically until the turbine gates are closed and the speed of the unit is less than 30 revolutions per minute. Automatic application of the brakes is intermittent with periods of time adjustable, until the speed has decreased to a predetermined level. The brakes are applied constantly thereafter until the unit is at rest.

Generators

The main and station-service generators are of the vertical type, totally enclosed and water-cooled. Generation is at 3-phase 60-cycle alternating current. Both main and station-service generators are of the conventional type with the thrust and upper-guide bearings located above the rotor and with a lower-guide bearing located below the rotor. The main generators are each rated 108,000 kva, unity power factor, 13,800-volts, and 120 revolutions per minute. The station-service generators are each rated 12,500 kva at 0.8 power factor, 6,900 volts, and 400 revolutions per minute.

The generators are provided with class *B* insulation for both the stator and rotor. The maximum temperature, however, is limited to 100 degrees centigrade which is 20 degrees centigrade below that permitted by the American Standards Association for class *B* insulation. This is industry practice for water-wheel generators of this rating.

Stators

The generator stator cores are built up of high-grade nonaging-laminated silicon steel with each lamination coated with insulating varnish to minimize eddy-current losses. The armature windings are wye-connected with main and neutral leads brought out of the stator frame so that differential protection may be provided for the generator. Two complete separate sets of windings are brought out of the machine in six main and six neutral leads. The six main leads are bussed into one 3-phase generator voltage bus structure. Current transformers are installed in the combined neutral leads for generator and generator-voltage bus-differential protection with additional current transformers in the split phase of the neutral for split-phase differential protection. The armature coils have an outer protective coating of semiconducting material for corona shielding. The armature winding is designed to minimize circulating current losses with attendant unnecessary heating. Temperature indication is provided by 10-ohm resistance temperature-detector coils imbedded in the armature winding.

Figure 8. Generator room looking toward equipment entrance

Figure 9. Generator room with one unit completed, others in progress

Rotors

The generator-rotor rims are laminated and constructed of steel plates bolted together to form a solid structure. The rotor spider is of cast steel and of 1-piece construction except for rotor arm extensions on six of the arms. These arms, three on diametrically opposite sides of the rotor, have extensions which are removable to provide shipping clearances. The rotor hub was shrunk on the generator shaft by heating the rotor hub and cooling the generator shaft. The pole pieces are of high-grade magnetic steel in the form of thin-punched laminations and are dove-tailed into the rotor rim laminations and held in place by means of tapered keys. The generator rotors are provided with amortisseur windings. The generators have a moment of inertia (WR^2), of about 175,000,000 which is higher than normal for stability purposes. The WR^2 of the generator plus the WR^2 of the turbine produces a regulating constant of 17,130,000. The regulating constant is a product of the revolutions per minute squared and the WR^2 divided by the horsepower rating of the turbine.

Electrical Characteristics

The remoteness of the Grand Coulee plant and the lack of system development in this region at the time the original generators were purchased necessitated considerable study to determine generator characteristics which would be suitable for any reasonable transmission requirement. It was assumed that long distance transmission would be involved with associated stability problems. The following characteristics were selected:

1. A rated current value of direct-axis transient reactance not exceeding 30 per cent.
2. Short-circuit ratio not less than 1.66 as determined by test.
3. The ratio of the calculated value of the quadrature-axis subtransient reactance to the calculated value of the direct-axis subtransient reactance not to exceed 1.2.

The characteristics have proved very satisfactory with the system as developed.

Excitation

Six of the generators have separate motor-driven exciter sets to provide full excitation at zero speed for use in starting the 65,000-horsepower synchronous-pump motors which will be used in connection with the irrigation project. The remaining generators are provided with direct-connected main exciters, and direct-connected self-excited pilot exciters mounted on top of the main exciters. The motor-driven exciters have synchronous motors. A d-c, compound-wound, self-excited pilot exciter is also connected to the common motor-generator shaft and provides excitation for the main exciter and the synchronous motor field. The exciters have class *A* insulation. Exciter capacity of not less than 110 per cent of actual requirements of the generator, when operating at its rating, was specified to provide for some variations from unity power factor. The exciters have operated continuously at considerably in excess of this output when the main generators are operated below unity power factor lagging and at considerable overload. In order to increase system stability, the exciter speed of response was required to be not less than 1.5. The speed of response for a normal machine is 0.5.

The motors of the motor-driven exciter sets receive their power supply from the station-service system. In order to assure sufficient torque to prevent loss of excitation due to momentary dips in voltage on the station power system, a pull-out torque of 250 per cent of rated torque was required in the motors.

Each main generator is equipped with an automatic voltage regulator including a voltage-sensitive master element, main-exciter field rheostat, pilot-exciter field rheostat, and voltage-adjusting rheostat. The voltage regulators are equipped with high-speed contactors for shunting in and out blocks of resistance during transient conditions. Each generator is provided with an exciter field breaker but generator field breakers were omitted.

Bearings

A thrust bearing located above the rotor was specified to facilitate bearing maintenance. The loading on the main generator bearing is approximately 2,000,000 pounds. Each generator is equipped with a Kingsbury-type thrust bearing with

Figure 10. 150,000-horsepower turbine scroll case nearing completion

Note many sections required in order to meet shipping clearances

babbitt on the stationary surfaces. Each of the bearing shoes is adjustable and is provided with a strain gauge for use in adjusting the bearings. The thrust bearings are provided with temperature detectors imbedded in the bearing metal for indicating the temperature of the bearings.

The thrust and upper-guide bearings of each generator operate in a common oil bath. Each lower-guide bearing operates in a separate oil bath. All bearings are of the self-oiling type requiring no external means for forcing oil between the bearing surfaces. All the oil baths require cooling and are provided with internal water-cooled heat exchangers.

Figure 11. 150,000-horsepower turbine runner enroute to powerhouse

Cooling

Each Grand Coulee generator is equipped with an enclosed cooling system with heat exchangers located inside the metal housing of the generator for removing the heat resulting from generator losses. The metal housing is sufficiently airtight to permit the use of carbon-dioxide gas fire extinguishing equipment. This equipment releases carbon-dioxide gas into the generator upon operation of the generator differential relays or whenever temperatures within the housing reach a predetermined level. The coolers are located around the stator frame and have sufficient cooling capacity to maintain the temperature of the air entering the generator at 40 degrees centigrade or less with one cooler out of service and the generator delivering rated output.

Brakes

Brakes are provided on the Grand Coulee generators of sufficient capacity to bring the generator and turbine rotating parts to a stop from one-half normal operating speed within $7^1/_2$ minutes. The brakes also serve as hydraulic jacks for lifting the entire generator and turbine rotating parts a sufficient distance to provide for removal or adjustment of the thrust bearing. Oil pressure for actuating the hydraulic jacks is provided by a motor driven high pressure oil pump.

Transformers

Transformers step up the voltage to 115 kv or 230 kv for transmission purposes. Seven banks of transformers are rated 13.6 to 230 kv, one bank is rated 13.6 to 115 kv, and one bank has three voltages, 13.6, 115, and 230 kv. The transformer banks are of the same rating as the generators and consist of single-phase, water-cooled, nitrogen-gas, cushion-type units. The impedance of the transformers is approximately 11 per cent. Some of the transformers are of the straight water-cooled type while others are of the forced-oil water-cooled type. The latter type represents the later trend in design of large power transformers.

Control

The main unit control features include the control, indication, instrumentation, protection, and annunciation at the unit control boards and at the main control boards. The unit control boards are located in the governor gallery adjacent to each turbine governor. The main control boards are located in the main control room. The main and unit control boards are operated as shown in the following.

Upon receipt of the signal from the operator in the main control room to start a unit, the operator in the governor gallery starts the unit auxiliaries and then starts the main unit and brings it up to

Figure 12. 108,000-kva generator rotor requiring the lifting capacity of two 350-ton cranes

normal speed and voltage. The operator in the governor gallery then signals the main-control-room operator who places the voltage regulator in service, synchronizes the unit with the system, and adjusts the load and voltage level as desired. The main control system includes the following.

Hydraulic Governor Control

Governor oil pressure is normally maintained at all times whether the unit is running or not by means of the motor driven oil pumps in the actuator cabinet. All control for starting and stopping the turbine, operating air brakes, controlling the speed, load limit, and speed droop settings are provided on the actuator cabinet located adjacent to the unit control board. A d-c solenoid is provided on the governor for automatically shutting the unit down by protective relays and by an emergency shutdown pushbutton on the main control board. The main control board has facilities for control of the turbine speed and turbine speed droop by means of selsyn devices, control of the load-limit device by means of a control switch, and for emergency shutdown of the unit. Indication of the position of the turbine gates and the load-limit device is provided on the main control board by means of selsyn devices.

Voltage Regulators and Excitation Control

Control of the excitation includes adjustment of the regulated generator-voltage level and placing the voltage regulator in and out of service. Instruments for reading pilot-exciter amperes and volts, generator-field volts, and main-exciter amperes are mounted on the unit control board. The main-exciter voltage is controlled by means of a motor-operated rheostat, with control switches at both the main and unit control boards. Means is provided at the main control board only for placing the voltage regulator in or out of service.

Equipment Protection

Relays of the differential type, with necessary auxiliary-tripping relays, furnish generator and transformer protection. On occurrence of a fault in the generator or connecting bus within the differential zone, the generator-differential relays operate and trip the high-voltage circuit breakers connecting the unit to the system and also trip the main-exciter-field circuit breakers, shut down the unit, and initiate the discharge of carbon dioxide gas into the generator housing. The operation of the transformer-differential relays performs the same functions as the generator-differential relays with the exception of the release of carbon dioxide gas.

A generator overspeed switch is arranged to close the turbine gates and operate the annunciator in case of overspeed. The outgoing transmission lines are protected by means of directional-distance relays and directional-ground relays, together with carrier-current type relays.

Load and Frequency Control

The load and frequency control consists of the following operating features which may be chosen by means of a selector switch.

1. Maintain system frequency and time error within the narrowest possible limits while using one or more generating units for this purpose or while regulating cooperatively in parallel with other existing power systems.
2. Operate about a scheduled output while contributing a predetermined adjustable amount of regulating assistance to the system.
3. Maintain a fixed output at any desired unit load.
4. Load division between units when operating in parallel on the same bus.
5. Permit parallel operation with other plants on the interconnected system, contributing an adjustable amount of regulating assistance to the system while operating about a predetermined tie-line load schedule.
6. Time error indication for each separate frequency controlled system.

Switching

The unit system is employed at the Grand Coulee power plant with the generators connected directly to the trans-

Figure 16. Generator-voltage bus structure of isolated phase construction with each conductor in a separate housing

formers without an intervening generator-voltage circuit breaker except for unit *L-1* which is connected to a 3-winding transformer bank through a generator voltage circuit breaker. The generator-transformer connection is made by means of an air-insulated, isolated-phase bus structure. An air space is provided between the metal enclosures practically eliminating the possibility of phase-to-phase faults. The generator neutrals are connected to ground through a potential transformer arranged to remove a generating unit from service and open the exciter field circuit breaker if a fault to ground develops. This equipment is to be replaced with a single phase distribution transformer with its primary connected between the generator neutral and ground. A resistor is connected across the secondary winding of the transformer. The capacity of the distribution transformer and resistor is each approximately equal to the capacitive kilovolt-amperes of the generator and its generator-voltage connections. The loading of the secondary of the distribution transformer prevents the occurrence of high-transient voltages caused by arcing faults or switching which might occur with the potential transformer grounding. The harmonics present in potential indication are also dampened making a lower setting of the ground relay possible. This and other advantages of the distribution transformer and resistor over the poten-

Figure 19. Grand Coulee power plant

Left power plant 230-kv switchyard and pumping plant. Single line diagram

tial transformer type of grounding made the change desirable for this important station.

All switching is accomplished at transmission voltage except for unit *L-1* and the switching required in connection with irrigation pumping. Six generating units in the left powerhouse will each furnish power at generator voltage to drive two 65,000-horsepower motors, for pumping irrigation water from Lake Roosevelt into the Grand Coulee balancing reservoir.

Generator *L-1* is connected to a 3-winding transformer stepping up to both 115 and 230 kv. Unit *L-9* is connected to a 115-kv transformer bank. These two generating units will furnish all of the energy required at 115 kv. All other transmission is at 230 kv. The 230-kv switchyard is arranged for a double bus system.

As the 230-kv transmission system grows with additional lines and generating units at Grand Coulee power plant, the switching problem becomes more complex. The present 230-kv bussing is unusual in that an interleaved system is used whereby the line reactances are used to limit circuit breaker duty. Half of the generators and half of the lines are on each of two busses. The lines tie these busses together and maintain system stability. This also has introduced operating problems due to the circuit breaker shortage during the war which results in each line of some of the pairs of lines having but one circuit breaker. When any line is out of service, system stability and switching limitations require three separate bus sections. This has required the installation of a loop circuit around the yard to tie the end bus section together.

The interleaved scheme is now being abandoned in favor of a ring bus having five sections. This requires circuit breakers of 10,000-megavolt-ampere interrupting capacity, but has advantages from a stability standpoint during system disturbances. The high cost of these circuit breakers dictated that only a minimum quantity of new circuit breakers be used. This is accomplished by using the second (auxiliary) 230-kv bus as a transfer bus, using only one circuit breaker for the second line of each pair of lines, using only one circuit breaker per generator, rebuilding present circuit breakers where feasible to 7,500 or 10,000 megavolt-amperes, tripping bus-tie circuit breakers to isolate a bus section when clearing a transformer fault.

Operation

The Grand Coulee power plant has operated successfully with the generating units carrying full load or overload almost constantly since their installation. Six main Grand Coulee generators were installed before and during the war, and two 75,000-kva generating units from Shasta power plant were installed temporarily during the war in order to relieve the power shortage. The Shasta units have been replaced by regular 108,000-kva generating units, and the last of the left powerhouse-generator installation completed this year. Six additional units are on order for installation in the right powerhouse.

Since the first generation at Grand Coulee, a power shortage in the Pacific northwest has been threatened and generator installation has been hard pressed to keep pace with the power demand.

The generating units have performed very satisfactorily, connected to the transmission system of very long lines indicating the characteristics selected for the equipment to be adequate. Loads of 240,000 kva and above have been carried on some of the transmission lines and 180,000- to 200,000-kva loads for one line are common.

Some difficulty has been experienced with the separate motor-driven exciters which obtain their power supply from the station-service system. Trouble experienced by the station-service system has caused the loss of excitation on the main generators. This has now been corrected by the use of a transfer switch which connects the exciter driving motor to another source automatically in the event of a power failure. The station-service system is also made more reliable by isolating it from the outside system. In order to insure a more dependable station service supply, a third source of station service is being made available by connecting a station service transformer to the *L-1* main generator bus.

Conclusion

The purpose of this paper was to outline some of the salient design features of the Grand Coulee power development under one cover. Much has been written about the different features, and the author wishes to acknowledge previous authors who have covered certain features of the power system design. The references contain further information about certain design features of this great project.

Discussion

E. F. Bossuyt and J. C. Page (General Electric Company, Schenectady, N. Y.): In this paper Denton has very effectively presented the features of this huge project which make it a noteworthy step in the generation and efficient use of hydroelectric power. It is particularly interesting to note the many features of this project which have either followed or dictated the most modern practices utilized in hydrogenerating stations. We refer to the use of the unit generation system, high-response excitation system, forced oil water-cooled transformers, isolated phase bus enclosures, and 10,000,000-kva interrupting capacity circuit breakers, to mention a few of the many modern trends followed.

The use of isolated phase metal enclosed bus, as in this station, is becoming more general, due largely to the high degree of reliability which it offers and ease of installation of this type of factory-assembled, generating-station bus. This type of bus is also very desirable from the standpoint of safety to operating personnel and ease of maintenance, being immediately accessible for inspection and maintenance. It has long been desired to obtain a factory-built station bus which would practically eliminate phase-to-phase faults, and now that such a bus is available in the form of this isolated-phase metal-enclosed bus, its use should find an important place in future large generating stations. The development of a similar type of isolated phase bus is presented in detail in another publication.[1]

A further indication of the adherence to modern trends is the use of forced oil water-cooled transformers which are proving their desirability especially at hydrogenerating stations.

The accepted exciter for large generators continues to be the direct connect edexciter. Separate motor-driven exciters are generally spares to the direct connected exciter, where used. Most motor-driven exciters installed since the Grand Coulee project have employed induction motors rather than synchronous motors. These induction motor exciter sets are normally supplied with flywheels.

The necessity and ultimate development of circuit breakers capable of much higher interrupting capabilities than those previously available was emphasized and achieved as a result of this large generating station. The increase in circuit breaker interrupting ratings to 10,000,000 kva was a great stride in the industry, which will undoubtedly influence the design of future large systems, and is a development which will henceforth be associated with the Grand Coulee project.

The following of modern trends and initiating of new methods of handling such large quantities of power have made this a unique modern power project.

S. E. Schultz (Bonneville Power Administration, Portland, Oreg.): Denton's paper presents an excellent description of the Grand Coulee powerhouse and sets forth very effectively the basic factors of historical and physical significance in connection with this tremendous development.

The Columbia Basin Project, which includes the Grand Coulee Dam and powerhouse, is so vast in scope and extent that it is difficult to fully appreciate its magnitude in terms of measurable standards. It is difficult, for example, to comprehend, on a purely statistical basis, such terms as 1,000,000 acres of new arable lands, 108,000 kw hydroelectric generators, 10,000,000-kva circuit breakers, and a powerhouse, when fully developed, with an output of over 2,000,000 kw measured in capability rather than rating. 1,000,000 acres would almost cover the state of Delaware, and it is quite evident that the Bureau of Reclamation is not only making history but also remaking geography in this major undertaking. 108,000 kw represents a fair-sized powerhouse. Yet, this is the capacity of only one generator, and there will be 18 such generators at Grand Coulee Dam upon completion of the powerhouse, now scheduled for December 1951. Actually, the generators now in service at Coulee have been producing at the rate of approximately 130,000 kw. In terms of available energy during an average water year, the Grand Coulee powerhouse could provide for the needs of New York City. To my knowledge, the largest circuit breakers built today carry a rating of 3,500,000 kva; yet 10,000,000-kva circuit breakers are required for Grand Coulee.

Additional statistics almost without end could be used to show the tremendous scope of the Columbia Basin project. Great as this development may be physically, there can be no question that its social implications are even greater. The effect of bringing into production this vast area of fabulously fertile farm land will substantially enhance the agricultural economy of the northwest and the nation. From the standpoint of power, the impact of Grand Coulee has already been realized in the tremendous development of industry in the northwest, and with it the material benefits to the nation as well as to the region. Largely because of this great power development along with Bonneville Dam, approximately 50 per cent of the aluminum of the country is now being produced in the northwest, whereas only eight years ago none was being produced. Other industries, including those related to chemical, agricultural, and lumber development, are finding new uses for power on a vast scale. The results are evident in the unprecedented growth of the Pacific northwest.

The Bonneville Power Administration is the marketing and transmission agency for the power output of Grand Coulee Dam, as it is for the power output of the Bonneville Dam which was built and is operated by the United States Army Engineers. These two projects, together with the Bonneville Power Administration system, serve as the federal grid in the Pacific northwest. Other federal projects will follow as the needs of the region grow. The present capacity of the grid is approximately 1,600,000 kw, of which approximately 1,100,000 kw is presently available from Grand Coulee Dam. It is expected that the capacity of this federal system will grow to approximately 3,600,000 kw in 1954, and perhaps as high as 10,000,000 kw in 1960. The technological and economic problems associated with this development will be formidable, but there is little question that these problems can be successfully solved, as evidenced by the progress made to date.

S. M. Denton: The author is indebted to Bossuyt, Page and Schultz, for their valuable additions to the interest of the paper. Agreement by Bossuyt and Page that this great project has followed and, in some instances, led the way in the most modern practices utilized in hydrogenerating stations is gratifying. Deviations from accepted modern practices were generally prompted by problems peculiar to this particular project. Direct-connected exciters are in use or proposed for all generators which will not be used for pumping. Six generators are equipped with separate motor driven exciter sets which were dictated by starting requirements of the 65,000-horsepower motors. In operation, two 65,000-horsepower motors are to be connected to one generating unit at standstill and brought to rated speed by the synchronous starting method. Synchronous motors were specified for the generator exciter sets in order to obtain high pullout torque which can be obtained at reasonable cost in synchronous motors. Induction motors will drive the exciter sets for the 65,000-horsepower pump motors. Here, however, loss of motor excitation is not considered as serious as with one of the large generating units. Induction motors have simpler controls and are preferable when the application is suitable.

Schultz' discussion added a very worthwhile picture demonstrating the magnitude of this development and brought out some of the social aspects and responsibilities in a project such as this. It greatly increases the value of the paper from an over-all viewpoint and adds a new field of interest.

Power System Overvoltages Produced by Faults and Switching Operations

AIEE GENERAL SYSTEMS SUBCOMMITTEE

POWER system overvoltages may result from lightning, switching, faults, loss of load, and other causes. An understanding of the phenomena associated with all causes of overvoltages is necessary in order to control the magnitude and to co-ordinate the protection and insulation levels of the system. Lightning may be considered the chief source of high overvoltages. Much attention and study has been and continues to be given to all lightning phenomena and means of protection. Next and of increasing relative importance are the overvoltages produced by faults and switching surges. Considerable study has been given this subject during the past 25 years and it is opportune to review the literature on power system overvoltages produced by faults and switching surges. This is the purpose of this report. Conclusions are drawn which indicate the progress and understanding to date and which may serve also as a guide to future investigations.

The results obtained from field tests on power systems are reviewed as well as the phenomena that control cumulative oscillations and restrikes. In addition, the results obtained by the miniature system method of analysis are given which show the influence of grounding, arrester location, and circuit breaker interrupter restriking.

Summary of Knowledge on Switching Surges

Early systematic investigation of system overvoltages was delayed because of difficulties encountered in field measurements and in calculations. Initial efforts to measure system overvoltages were directed principally to the securing of information on lightning which, incidentally, gave valuable data on switching surges. Not until 1924 through the use of "Lichtenberg" figures as a method of voltage measurement on power systems were there much field data obtained on switching surges, and not until after the introduction of miniature system methods in 1937 was the determination of system overvoltages produced by faults and switching operations generally facilitated.

Measurement of Switching Surges on Power Systems

The spark gap was the earliest device used for the measurement of system overvoltage. However, the first really practical devices were the klydonograph and the surge voltage recorder.[1-4] In these devices, a voltage proportional to that to be measured on the transmission system is impressed on a photographic film by a set of point-to-plane electrodes. The record appears on the film in the form of "Lichtenberg" figures, which can be calibrated to give data as to polarity, magnitude, and duration of the surge. The addition of a clock mechanism to drive the photographic film adapted the instrument for measuring overvoltages during normal system operation. From the "Lichtenberg" figure measurements, a great amount of data on switching surges has been obtained. The accuracy of the measurements has been limited and the results therefore are of somewhat questionable value.

Progress in lightning studies led to the application of a more accurate instrument—the cathode-ray oscillograph.[5-9] To obtain information on the magnitude of surges during normal operation of a system, special electronic relays were used to make the oscillograph inoperative except for surges in excess of a predetermined magnitude. In the laboratory the device produces very satisfactory records of the magnitude-time characteristics of system overvoltages. In the field the cathode-ray oscillograph is cumbersome and expensive when used as a surge recorder for obtaining overvoltages during normal operation of a power system. However, it is more applicable to set system tests.

Mention should be made also of other forms of surge recording devices that have received limited use. The magnetic oscillograph is a very satisfactory device for recording overvoltages in prearranged tests, provided the natural frequencies of the system are sufficiently low with respect to the natural period of the oscillograph element.[10] Vacuum tubes have been used also which permit current flow when a given voltage is exceeded, this current being used to actuate an operation counter or other recording device.[10] A few vacuum tube devices have been used, principally for the lower voltage systems that are below the range for successful operation in obtaining "Lichtenberg" figures. More recently the magnetic link recorder,[11,12] which has been used successfully for measuring the crest current in a lightning surge, has been adapted to record the maximum voltage of a switching surge.

Paper 48-124, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21-25, 1948. Manuscript submitted February 2, 1948; made available for printing March 9, 1948.

Overvoltages Obtained During Field Tests on an Overhead Power System

An early extensive report of switching surges on transmission systems was published in 1925 in which the data were obtained by means of flashovers of needle gaps on photographic film and the klydonograph.[18] In 1927 and subsequent years, other extensive investigations were published.[8,9,14–17] The results of these representative field studies indicated by the reference numbers were presented mostly in tabular form. Later investigators prepared summaries of the published data, and these together with reproductions of some of the results from the representative studies are shown in Figures 1 to 9. It is to be noted that all curves except Figures 5 and 6 have times normal crest line-to-neutral voltage as ordinate. It is to be noted also that the percentage distribution curves, Figures 1 to 4, do not have a common overvoltage reference base at 100 per cent on the abscissa. For example, in Figure 1, the percentage distribution starts with overvoltages of two times normal at 100 per cent, disregarding all the surges of a magnitude less than twice normal. This was done in preparing these summary curves in order to give a more suitable scale for plotting the results of the surge studies. In Figure 2 the base voltage is two and one-half times normal and in Figures 3 and 4 one times normal.

The investigations which covered a large number of systems and several years of operation provided data on the magnitude of surges, identification with type and location of switching operation, and point of measurement. The data also included similar information for surges resulting from faults and the consequent fault-clearing operations. For comparison a summary of lightning surge data as to magnitude and frequency of occurrence is shown in Figure 3. Data on the magnitude of switching surges appearing at various points on a system as a result of de-energizing a line are shown in Figures 5 and 6. All investigators report that a de-energizing operation on a line produces surges of greater magnitude than from an energizing operation.

The characteristic of switching surges summarized in Figures 1 to 6 were obtained on systems of various characteristics from the standpoint of grounding.

The Joint Development and Research Subcommittee of the Edison Electric Institute and Bell Telephone System[18] made an extensive investigation for the correlation of system overvoltages and system neutral grounding impedances. As part of this study it examined the previously reported data from which Figures 1 to 6 were obtained. In addition, the results of observations made on several systems ranging from 26 to 140 kv were given. Figures 7 to 9 summarize the results on three of these systems in the form of scatter diagrams. The dotted straight lines in these three figures were statistically derived to determine the degree of correlation between the observed voltages and the distance between the point of observation and the fault. In the event of a ground fault the crest voltage on sound phases rises to a higher value for ungrounded systems than for systems grounded through a low impedance. The Joint Development and Research Subcommittee found that the sustained fundamental frequency overvoltages had an important bearing on the total crest voltages to ground that would be obtained. The maximum surge voltage of six times normal reported in Figures 1 to 3 may be limited by the wet flashover of the line insulators.[19] In lightning-arrester protected systems where lightning-arrester operation could have occurred, the maximum surge voltages would have undoubtedly been appreciably below six times normal.

Overvoltages Obtained During Field Tests on Cable Systems

Relatively little data concerning voltage transients on cable systems are available. Some results from studies on six combined cable and open-wire systems and eight "pure cable systems" are shown in Tables I and II.[14] In general it is indicated that switching operations on cable systems produce substantially lower surges than on open-wire systems.

The history of switching surges on the Chicago (Ill.) 12-kv system experienced during the period from 1919 to 1938 was reviewed and published,[20] and Figures 10, 11, and 12 are results from this study. Spark gaps and needle gaps were used in obtaining these data. The gaps were calibrated by breakdown and a recording meter indicated the existence of a surge. By correlation between the gap setting and time of occurrence of a surge, determination of the percentage of surges exceeding a given voltage became possible.

Table I and Figures 10 and 11 demonstrate that high surges accompany cable failure. In some cases coincident with a fault in the system a fault at another location occurred. This presumably was caused by the effects of voltage surges initiated at the first fault and acting on a progressively weakened cable insulation, or from cumulative increases in voltage produced by a circuit breaker restriking upon interrupting charging current of the cable. On the Chicago system during the period of observation 4.85 per cent of 1,240 primary failures were accompanied by one or more simultaneous faults. In no case did the surge exceed 3.5 times normal voltage. On systems with a combination of open-wire and cable surges higher than three times normal occurred, as shown in Table II. In Table I it is shown that faults and interruptions have substantially higher ratios of high surges than do other causes. It is surmised that the voltage of such surges is increased because of the confined path for cable puncture. Weakened insulation of aging cables and restriking circuit breakers are assumed to be a contributing factor in the production of simultaneous faults reported in the operating experience of cable systems. Switching surges are of importance on cable systems because of the large investments involved.

Overvoltages Obtained from Special Investigations of Switching Surges

In recent years there have been relatively few field investigations of the general problem involving the production of overvoltages as a result of switching operations or faults on power systems. Such work has been directed principally to determining the magnitude of overvoltages encountered in particular systems or with particular types of switching disturbances. There have been, however, two general investigations; namely, interruption of charging current, and transients in electric furnaces.

High-voltage circuit breakers are required to interrupt fault current quickly in eight cycles or less. They are also called upon to interrupt charging current for long sections of high-voltage lines. Considerable attention has been devoted recently to the transients produced by such switching operations since the surges are of low frequency and contain a great deal of energy. Thus they can permeate the entire system. These transients can be minimized by the use of stored energy type circuit breakers,[21,22] or the use of resistance elements shunting a portion of the interrupter. This latter means limits the number of restrikes and reduces the overvoltages produced when restrikes occur. Some test results showed on the

(*Figure 4, reference 20*)

* The dotted straight lines or regression lines were derived statistically to determine the degree of correlation between the observed voltages and the distance between the point of observation and the fault. Scattering of the points causes the lines to diverge and they would be 90 degrees to each other when there is no correlation among the points of the diagram. If all points fall on a straight line the regression lines will coincide and also pass through all the points.

bus side a maximum voltage to ground at the switch of 1.9 times normal on de-energizing a 130-mile section of a 220-kv solidly grounded system.[23] Also it was reported that maximum voltages to ground for de-energizing a similar length of 220-kv line operated with solid grounding or with a ground fault neutralizer were as follows:

Maximum Voltage	Without Shunting Resistor	With Shunting Resistor
Ground fault neutralizer	4.4	2.0
Solidly grounded	1.8	1.3

In a recent paper, the results of tests made on a system of underground cable and overhead line to determine a design of the resistance shunting elements for the interrupters of the circuit breaker were described.[24] These studies were made to prevent possible failure of lightning arresters from voltage surges caused by restriking in the circuit breaker when switching, essentially, a capacitive circuit of cable and overhead line.

In another recent paper, results are given of many tests which showed that the maximum voltage at the bus on de-energizing long transmission lines did not exceed 2.5 times normal on a solidly grounded system and 4.4 times normal on a neutral reactor grounded system using circuit breaker designs without effective arc controlling means for the lower current values. With arc control means capable of limiting the number of restrikes to one or less during charging current interruption, the bus voltage on solidly-grounded systems did not reach two times normal.[25]

Mention should be made of investigations on the switching of large capacitor banks, which is closely related to the problem of interruption of charging currents, except for the differences that arise as a

result of lumped capacitance in a capacitor bank in comparison with distributed capacitance on the transmission line and for the frequency of circuit breaker operations involved.[36]

The transient overvoltage incident to the operation of electric furnaces has been investigated by the AIEE subcommittee on transient voltages in arc-furnace circuits.[37] From Figure 13 and other data, the subcommittee concluded on the basis of voltages encountered in the supply system that the surges are similar to those produced by ordinary switching operations except for the increased frequency of occurrence. These transient overvoltages in arc-furnace installations occur during the melting-down operation and at the time of opening or closing the furnace circuit breaker. The highest magnitudes appear to be associated with circuit breaker opening operations. Mention should be made also of a special case reported when transients were minimized by elimination of a short section of cable in the primary supply as shown in Figure 14.[38]

There are in addition other special applications and unusual operating conditions which may give rise to overvoltages such as overspeeding of generators when disconnected from loads, or such as those resulting from the third and fifth harmonic components of voltage generated

in a synchronous machine having unequal rotor impedances when an unbalanced fault occurs on overhead transmission lines with an appreciable amount of line charging capacity and when the lines were disconnected from the system or load.[29,30] In this latter case the harmonic overvoltages are known to be determined principally by the ratio X_q''/X_d'', the magnitude of the abnormal voltages increasing as this ratio increases from unity. Damper or amortisseur windings can be used effectively to reduce this ratio and prevent these abnormally high voltages. Rational design of apparatus and systems to prevent sustained overvoltages is essential to eliminate damage of lightning arresters and make possible the coordination of insulation levels and make possible a reduction in insulation levels at the higher voltages. Other similar conditions of overvoltage have been discussed by the AIEE committee on protective devices in its report "Correlation of System Overvoltages and System Grounding Impedances."[31]

Mention should be made of the AIEE report by the Subject Committee on Present-Day Grounding Practices, containing a review of operating experiences by numerous power systems with different grounding methods.[32] It is indicated that on a basis of the ratio of those systems reporting double-faults—simultaneous or consequential—to the total number of systems covered in the report,

about one-fourth of the ground-fault neutalizer systems, ungrounded systems, and resistance grounded systems reported double faults, whereas less than four per cent of effectively solidly grounded systems reported this type of trouble.

Results from Systems in Miniature

Prior to the accumulation of the principal data on switching surges, investigations had been started to determine the mechanism of cumulative oscillations and the phenomena involved in the interruption of an arc and its restriking.[33,34] These studies showed that high overvoltages could be produced by alternate establishment and interruption of an arcing path, if restriking takes place at successively higher values of voltage. The phenomena involved in restriking were shown to be dependent upon the intersection of two curves, one representing the magnitude-time characteristic of system recovery voltage across the former arc path and the other the magnitude-time characteristic of dielectric recovery strength in the arc path following a current zero.[35]

System-recovery voltages can be measured on a cathode-ray oscillograph on an actual power system in the field or on a miniature system in the laboratory.[36,37,38] The recovery voltage also can be calculated by theoretical methods, but the complication and tediousness have prevented analysis of sufficiently complex systems as to represent practical conditions.[38,39] The limitations of the foregoing methods were overcome by a method of analysis based on the use of the miniature system.[40,41] In this method the system under consideration is set up in miniature with sources of voltage and lumped constants of inductance, capacitance, and resistance to represent corresponding elements of the actual power system. Circuits with distributed constants are simulated by combinations of lumped inductance and capacitance elements. Switching operations are performed on the miniature system which correspond to the circuit change to take place on the actual system. Typical investigations in which the miniature system method has been used are the following.

1. Protector-tube recovery voltages.[42,43]
2. Transient overvoltages during faults.[19,44,45]
3. Arcing grounds.[19,46]
4. Circuit breaker restriking.[19,33,46,47]
5. Effect of lightning arresters in limiting overvoltages.[48]
6. Effect of transformer saturation in limiting overvoltages.[48,49]

In Figure 15 and Table III are summarized data from some of these investigations. Figure 15 shows the effect of grounding impedance on transient voltages caused by de-energizing (1) an unfaulted line, (2) a line with a single line-to-ground fault, and (3) a line with a double line-to-ground fault. The transient voltages are produced by one or by two cumulative restrikes in the interrupting circuit breaker. Table IIIC also shows the transient voltages caused by switching indicating the maximum values that may be experienced in the faulted or unfaulted phases. The values recorded are those produced by two restrikes in the circuit breaker under the conditions leading to the highest overvoltages on systems in which the system neutral is isolated, effectively solidly grounded, or grounded through a ground fault neutralizer. For the same conditions of grounding Table IIIA shows the fundamental frequency steady state voltages whereas Table IIIB shows the maximum transient voltages that may be experienced when a solid fault occurs on a system. Figure 15(*D*) and Table IIID show the overvoltages that could be produced by arcing grounds provided the postulated conditions of arcing and of recovery of the air dielectric were obtainable. The voltages shown in Figure 15 and Table III are those obtainable when no voltage limiting protective devices such as lightning arresters have been employed. These results demonstrate:

1. The magnitude of the steady-state fundamental-frequency overvoltage is directly associated with the arrangement of the system neutral and the type of fault. The lowest overvoltages are obtained on the effectively grounded system ($X_0/X_1 \gtrless 3$). The highest overvoltages are obtained on the isolated neutral system with single-line-to-ground faults and may be of the order of 1.73–2.1 times normal line-to-neutral crest voltage. The grounded system may approach 1.4 times normal.

2. The transient overvoltages during solid ground faults are always less than twice the steady-state overvoltages reached under the same fault condition. The maximum values are of the order 2.7 to 3.5 times normal on the isolated neutral and 1.7 times normal for the grounded neutral system.

3. Voltage surges of sufficient severity to damage equipment are obtainable for a large variety of system conditions during the interruption of line charging current when circuit breakers are used with no effective means to eliminate or minimize a possible process of cumulative restriking within the circuit breaker. The maximum voltages that may be experienced from two restrikes are of the order of 5.5 and 4.5 times normal for the isolated neutral and the grounded neutral systems respectively. It is to be emphasized that even under fault conditions one or two phases may interrupt only line charging current. These overvoltages are approximately the same as the maximum values recorded from field tests.

Where the lightning arresters limit the switching surge voltages, it is indicated that switching surge voltages should not exceed the sparkover voltage of the lightning arrester which, in an effectively solidly grounded system ($X_0/X_1 \gtrless 3$) should be the order of 2.5 times the line-to-neutral voltage or approximately the 60 cycle sparkover voltage. With lightning arresters being operated by switching surges it is shown that as a consequence the severity of the discharge on the lightning arrester in some systems can be of equal if not of primary importance as compared with expected lightning surge discharges.[48]

It is of interest to point out that the production of cumulative oscillations requires a dielectric recovery voltage curve for which the magnitude increases with time from the first current interruption. This characteristic is radically different from that obtainable on the ordinary line insulator of a transmission system. To date no oscillographic evidence of this characteristic has been observed[50,51,52] except during certain types of circuit interruption with circuit breakers.[33,47] The opinions that this characteristic can be obtained by a fault in solid insulation are based on insulation flashovers difficult to account for in any other manner, rather than on more direct evidence. There is also no evidence to date that an arc as a circuit element either in a circuit breaker or in a line-to-ground fault can produce overvoltages as the result of its nonlinear characteristics, although it has been postulated theoretically.[53,54,55]

On the basis of experimental evidence from the field and of miniature system studies the magnitude and severity of switching surges can be reduced as a factor in the insulation requirements of apparatus and lines by the following means:

1. Effectively grounding system neutrals ($X_0/X_1 \gtrless 3$).
2. Rational application of lightning arresters.
3. Switching short sections of line.
4. Switching lines on the low side of transformers.
5. Switching with stored energy type circuit breakers or with resistance shunting of the circuit breaker contacts.
6. Switching with circuit breakers designed to interrupt charging current with not more than one restrike.

Perhaps the principal advantage of the miniature system method is that it pro-

vides a rational approach to the problems of overvoltages to be expected for a wide range of system constants and grounding impedances. Results of this approach are more understandable and, no doubt, more useful than could be obtained from field data which are incomplete because such data cannot cover a great range of system constants or switching conditions.

Conclusions

1. Maximum switching surge voltages on overhead lines or cables are the consequence of the interruption of fault currents and/or the de-energization of an essentially capacitive circuit.

2. Maximum switching surge voltages of six times normal may be experienced on overhead lines. The maximum values experienced are perhaps limited by the flashover of insulators or bushings on systems where there is no lightning arrester operation from switching surges.

3. Maximum switching surge voltages of three and one half times normal may be experienced on cable systems in which no arrester operation is involved.

4. Items 2 and 3 of the foregoing are based largely on data accumulated since 1924 from measurements using gaps or the "Lichtenberg" figure principle of measurement and which therefore are of limited accuracy.

5. Transient overvoltages incident to the operation of electric furnaces are similar to the surges experienced on an overhead line except for the increased frequency of occurrence. The highest magnitudes appear to be associated with circuit breaker opening operations.

6. Direct evidence to date indicates that switching surges of the greatest severity on systems occur only from circuit interrupting devices wherein a process of cumulative restriking of an arc occurs at successively higher voltages as the result of an increasingly greater dielectric recovery strength. No direct evidence exists that this process occurs from arcs in open air or in solids.

7. There is no evidence to date to indicate that the nonlinear characteristics of the arc enters in as an important factor in system overvoltage.

8. The method of analysis using system representation in miniature, provides a rational approach to the problem of overvoltages and gives results that are more understandable than can be obtained from field data.

9. Results from the study of systems in miniature show that the magnitude and severity of the switching surge may be reduced by the following:

a. Effective grounding of system neutrals.

b. Rational application of lightning arresters.

c. Use of circuit breakers that have a minimum tendency to restrike.

d. Switching short sections of line.

e. Switching lines or cables on the low-voltage side of the transformers.

10. In lightning arrester protected systems, the switching surge voltage should not exceed approximately the 60 cycle sparkover voltage of the lightning arrester. For a solidly grounded system ($X_0/X_1 \cong 3$) this value is about 2.5 times normal line-to-neutral voltage.

11. In lightning arrester protected systems involving long lines, the severity of arrester discharge from switching surges can be of primary importance as compared with probable lightning surge discharges.

12. In lightning arrester protected systems the switching surge does not appear to be an important determining factor in the insulation requirements of apparatus or lines.

Discussion

Alexander Dovjikov (Bonneville Power Administration, Portland, Oreg.): The report is a very timely contribution to the art, and particularly so now when the tendency of large hydroelectric systems is to increase the reach of their high-voltage transmission lines. In order to do so economically, lines should be loaded more heavily than in the previous practice, and the lines should be designed with maximum use of materials commensurate with safe practice. An important item in decreasing the capital investment is the decrease of the insulation level of lines for voltages 230 kv and higher, and a review of causes of overvoltages on the system and of the measures to decrease them if not to eliminate them altogether is a fundamental approach to the problem. So far, the minimum amount of line insulation was based on extrapolation from low-voltage rules as given by the National Electrical Safety Code, approved by the American Standards Association, and it seems that this extrapolation is too far reaching and that the rules should be based on a more substantial engineering approach to the problem; a correct approach can be based naturally only on such work as presented by the subcommittee and on the experimental work on voltages above 230 kv being conducted in this country, in France, and in Sweden.

The system insulation must be co-ordinated, and such co-ordination begins usually with selection of the lightning arrester level. In so far as protection from lightning is concerned, we will give the benefit of doubt to the lightning arrester ability to protect the system from all but the most severe direct strokes accompanied by long waves. We are not certain, however, about the lightning arrester's ability to discharge overvoltages produced by certain faults and by switching operations, and the report recognizes that the surges produced by them "are of low frequency and contain a great deal of energy." Accordingly, conclusion 11 of the report states that "the severity of lightning arrester discharge from switching surge can be of primary importance as compared with probable lightning surge discharges." We agree that the correctly designed and correctly selected lightning arrester will protect the insulation on the first discharge impulse, but will the lightning arrester protect itself from destruction? Without a reasonable assurance (proved not only in the laboratory but also under actual operating conditions) that the lightning arresters will stand up in at least a large majority of transient over-

voltages that may be expected on the system, they cannot be taken as the basis for selection of lower insulation level on long, high-voltage lines with pronounced capacitance. We are not familiar with such investigations, and the extensive bibliography of the report hardly mentions any published work on the subject.

The line insulation must be above the sparkover voltage of the lightning arrester and above its voltage drop when discharging heavy currents; the seal-off voltage must be naturally above its 60-cycle voltage. The character of system grounding, or to be more exact the value of X_0/X_1, determines whether 80 or 100 per cent lightning arrester should be used. There is no magic, however, in the value of 80 per cent, and even a lower figure may be selected. The lightning arrester voltage rating, as determined by the ratio X/X_1, controls its protective level, and this value in turn governs the selection of station insulation level. The wet flashover of insulators, which should be assumed contaminated, must be above the lightning arrester protective level. How much higher? The insulator string should be of such dimension that no appreciable corona would appear on the insulator adjacent to the conductor, and the string should withstand the voltages appearing at the lightning arrester with a reasonable margin even when insulators are contaminated and one or two of them (depending on experience and adapted safety factor) has been damaged. If line insulation is reduced for a given degree of grounding and ground-wire protecton, a large number of outages due to insulation flashover and subsequent switching should be expected.

To what extent it is permissible is determined by the degree such switching affects the transmission of power, that is, speed of fault clearing, availability of reclosing, its type and speed, the number of parallel transmission circuits, and the relative change in transfer impedance produced by switching of faulted sections and other factors of maintaining transient stability of the system.

It is true that outside of some isolated cases the lightning arresters have stood up pretty well in the less extensive systems, and it may be reasoned that the switching surges were also taken care of. The increased extension of transmission systems, and the more frequent use of higher transmission voltages increase the possibilities of more frequent and more severe switching surges; these, particularly in connection with the proposed lowering of insulation levels, and the lower protective level of lightning arresters, require careful checking to insure against failure of existing lightning arresters.

The situation with lightning arresters resembles that with high-voltage transformers. Notwithstanding the fact that the transformers even of older construction had a very good operational record, new designs and new methods of insulation testing (impulse voltage) were introduced, and this line of approach is highly recommended for studies of operations and new developments of lightning arresters, which apparatus becomes more basic and therefore more important than ever.

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The committee's report contains very valuable information and is a needed addition to the data on this important subject. With the increased use of cable, as well as longer overhead lines of extra high voltage, further studies will undoubtedly be warranted.

In the second paragraph under Section I (*D*), the statement is made that switching transients may be minimized by the use of stored-energy type circuit breakers or the use of resistance elements shunting a portion of the interrupter. A similar effect would be obtained from oil circuit breaker interrupters of the self-generated pressure type when provided with supplementary stored energy pistons to assist in the interruption of low currents.

Although it is generally true, as the report states, that de-energizing operations on a line or cable produce surges of greater magnitude than from energizing operations, it should be noted that, as shown by field tests, energizing transients superimposed on an already charged line or cable recently disconnected and left isolated may result in surge crests greater than obtained when de-energizing, even with a highly effective interrupter.

It appears that consideration, therefore, should be given to draining off such charges, particularly from an isolated cable of some length, before re-energizing.

S. B. Crary (chairman, AIEE general systems subcommittee): The discussions by Leeds and Dovjikov pointed out considerations which either have not been completely considered or which are outside the scope of the subcommittee report.

Leeds suggests that consideration should be given to the energization of isolated cables, and in particular to the draining off of the electrostatic charge. The residual electrostatic charge will be drained off more rapidly if switching is done on the low side of the transformers. In any case, it is necessary as Leeds has pointed out to consider the residual electrostatic charge and the rate at which it is drained off prior to re-energization.

The discussion by Dovjikov points out the importance of many other factors which it was not possible to include in the subcommittee's report. The problems which he mentions are important ones and some of them are being given careful consideration by other groups. It was the intent of the subcommittee report to confine itself to the magnitude of power system overvoltages and not to attempt to determine, for example, the amount of insulation required on the line or the specific conditions under which the lightning arresters may be damaged. It was pointed out, however, that the possibility for damage of the lightning arrester is reduced when the circuit breaker involved has a minimum tendency to restrike.

Mobile Radio

AUSTIN BAILEY
MEMBER AIEE

MOBILE radio as discussed in this paper will consider systems for extending voice communication to automobiles, trucks, and other vehicles. Radio-telephone communication with automobiles appears to have had its beginnings in the period immediately following World War I, at which time the motor car was assuming greater importance. Although law enforcement agencies were quick to adopt motor vehicles to increase their own mobility and effectiveness, it was apparent almost from the beginning that the police call-box wire telephone system which had worked well for the foot patrolman could be supplemented to advantage to meet the needs of motor patrols. One of the first applications of radio-telephony to automobiles, therefore, was in the field of police communication. Thereafter the success of these systems led to use by others having need for communication with automobiles, such as construction and repair trucks of power companies, fire and ambulance vehicles, busses, delivery trucks and taxicabs. Subsequently, mobile service was provided for the general user having need for telephone communication from motor cars by means of a common-carrier type of mobile service.

Early Police Radiotelephony

The first experiments in radio communication with automobiles appear to have been made in Detroit by the Detroit police department, during 1921. These experiments involved one stationary installation, called a "land station" in present-day terminology, and one radio-equipped car. The early experiments were not too successful, owing to the limitations of the radio apparatus then available for mobile use, and little further was done in the field of motor car communication at that time. In 1927, the Detroit police department renewed its experiments and by April of 1928 had a mobile radio communication system in successful operation.

The police department of Berkeley, Cal., independently conducted experiments with motor car radio communication in 1927, and in the spring of 1928 also had a radio system in operation in the neighborhood of 2,000 kc. It is reported[1] that the police cars in Berkeley were signaled by flashing neon lights and the officers were instructed by code to don earphones for secret messages or turn on loudspeakers for general broadcasts.

About this time a novel police radio system was improvised in Chicago.[2] Broadcast receivers were installed in police cars and radio broadcasting station *WGN* interrupted its programs to give messages to the police. This system soon turned out to be of as much value to criminals as to their pursuers, and gave way before long to an extensive police communication system patterned after the Detroit system.

Mobile radio for police was coming into general use in other parts of the western hemisphere as well. In the summer of 1933, the federal authorities in Brazil inaugurated a radio system at Rio de Janeiro for communication with motorcycle patrols and harbor craft of the marine police.[3]

The growth of municipal police radio was rapid indeed. By the end of 1929, 15 cities in the United States had one-way radio communication with police patrol cars, and two years later the total had grown to 70. In September, 1934, it was reported that 130 municipalities in eight states had police transmitters and about 4,000 police cars carried receivers.

The typical police radio system in operation about 1930 consisted of a small land transmitter, 500 watts or less, and a number of mobile receivers in automobiles. Operation was on a frequency in the 1,500–2,500 kc band. Usually the transmitter was installed in police headquarters, where the functions of the radio operator and police dispatcher could be performed by a desk sergeant or by the police telephone operator. The equipment was generally put on the air only for announcements, and not left on continuously as in broadcasting practice. Car receivers obtained filament voltages from the car battery and plate voltage from dry "B" batteries.

In the early 1930's it became increasingly apparent that the one-way nature of the communications from the land station to the mobile units was a serious limitation to the effectiveness of police radio. The opening of experimental frequencies in the 30–40 megacycle band at this time, although done primarily to make more channels available and relieve overcrowding on the medium frequencies, stimulated experimentation with small transmitters on cars, since at the higher frequencies the dimensions of a suitable radiating system became small enough to be applied to a motor vehicle.

Experiments with these mobile transmitters gave promising results, although with techniques available at the time the ranges obtained were seldom greater than three or four miles. These short ranges made it necessary to employ a number of land receivers, connected to the central operating point by wire lines. The quasi-optical nature of transmission at these frequencies placed a premium upon antenna height at land receiver sites and substantially line-of-sight transmission paths between cars and land stations.

Experiments having proved the utility

Paper 48-125, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 28, 1948; made available for printing March 10, 1948.

AUSTIN BAILEY is with the American Telephone and Telegraph Company, New York, N. Y.

Much of the material presented in this paper has been contributed by other engineers in the Bell System. To them the author wishes to extend due credit, and in particular to C. M. Smith and R. H. Johnson of the American Telephone and Telegraph Company who assisted him in the compilation of this material.

of the 30–40 megacycle band for car-to-land transmission, manufacturers were not long in building and installing the new equipment. Some police departments supplemented their existing medium-frequency land-to-car systems with the higher frequency car-to-land installations, while others elected to employ the higher frequency equipment for both directions of transmission. According to one periodical,[4] the first commercial two-way installation for police use on these higher frequencies was made in the early summer of 1933 in Eastchester, N. Y. Another early two-way installation was made for the Bayonne, N. J., police department using a frequency of 34.6 megacycles, with 25 watts power at the land station and 4.5 watts in the police cars.[4] Power utilities, traction companies and others having use for emergency communication with their repair trucks also were providing radio-telephone installations. An installation for emergency radio-telephone service which for the first time provided connection from moving vehicles to any telephone was established in New York City and began operation on December 5, 1940.

The Beginnings of Modern Mobile Systems

In 1939, experiments indicated that frequency modulation (f-m) held much promise and appeared to be superior to the conventional amplitude modulation (a-m) universally employed up to that time for radio-telephone service from vehicles. In addition to giving some reduction in received noise, f-m was demonstrated to be capable of reducing the "flutter" noticed when receiving a-m signals in a vehicle moving at high speed. Thus f-m appeared to be particularly applicable to mobile radio.

Much of the pioneering work in f-m mobile radio was done in developing a state-wide radio system for the Connecticut state police.[6,7] The development work was begun in July, 1939, and the following year the system was in operation, using a frequency of 39.18 megacycles for car-to-land transmission and 39.50 megacycles for land-to-car and car-to-car. The use of two-frequency mobile units in this frequency range was in itself an innovation, as police systems in general had been operated previously on a single-frequency basis with car-to-car communication on the same channel as land-to-car transmission. The 2-frequency system provided greater flexibility of operation in the territory covered by a single land station, but its principal merit was that it permitted the various land stations to carry on their separate activities simultaneously without serious interference. Being on a separate frequency, the low-powered mobile transmitters in poor locations did not have to compete with land transmitters in nearby areas advantageously located on mountain tops.

While Connecticut was pioneering in f-m for state police use, the city of Chicago in March of 1940 was deciding on f-m mobile transmitters after a comparison trial of both f-m and a-m equipment.[8] Following the lead of Chicago and Connecticut, others turned to f-m, and most manufacturers of mobile radio equipment converted their production to f-m. The manufacture of a-m mobile systems was all but discontinued, a very small quantity of a-m equipment being produced chiefly for replacement purposes.

At this point World War II intervened and the full output of all radio manufacturers was diverted to military purposes. Although the war appeared to be a period of enforced inactivity, in so far as progress in civilian mobile radio was concerned, the rapid advances in electronics under the impetus of the war held a promise for future improvements of great significance.

Modern Mobile Radiotelephony

Advanced techniques, overcrowding in the 30–40 megacycle band, and opening of the 152–162 megacycle band all contributed to a move toward still higher frequencies by manufacturers and users alike. The 152–162 megacycle band, with its relative freedom from noise and long-range interference, and with other desirable advantages such as a car antenna less than 18 inches long, was extremely attractive. The facilities of manufacturers were taxed by the demands of police, and by power companies, taxi operators, and others.

Typical Present-Day Mobile System for Small Areas in the United States

The antenna most commonly used for small systems is a single coaxial dipole radiator, fed through an air dielectric or solid dielectric coaxial line. Formerly air dielectric was more popular, but with the development of low-loss solid dielectric line which will not increase its attenuation with age, the solid dielectric line is finding increasing favor. Where coverage requirements are unusually stringent, vertical directivity, obtained with a 2-bay or 3-bay stacked antenna, may be employed in place of the simple dipole to increase the effective radiated signal in the horizontal plane. For special coverage configurations, reflectors and directors are sometimes used to obtain horizontal directivity.

Operation of a small radio system is usually on a single-frequency basis as indicated by Figure 1; that is, all land and mobile transmitters and receivers are tuned to a single frequency. This permits communication car-to-car as well as land-to-car and car-to-land. If the community is one of a cluster of small municipalities, and if the given channel assignment is repeated in a nearby town, then it is customary to resort to 2-frequency operation to reduce interference. The land transmitter and mobile receivers will be on one frequency and the mobile transmitters and land receiver on another.

The usual small station employs a combined transmitter-receiver unit mounted in a console and installed on the back of a desk. The console cabinet contains, in addition to the transmitter chassis and receiver chassis, a loud-speaker, antenna transfer equipment, operating keys, pilot lights, and possibly meters. The radio transmitter-receiver-console for a small radio system is frequently installed adjacent to the telephone switchboard. By this arrangement the switchboard operator may also function as dispatcher-radio operator.

The operator may employ a telephone handset with push-to-talk button, or a desk stand microphone. The microphone may be used in conjunction with a transmit-receive key, a push-to-talk button, a foot switch or a knee-actuated talk switch. The loudspeaker is generally arranged to be in operation continuously; however, if a telephone handset is used, there is an option of muting the speaker when the handset is removed from its cradle.

The land transmitter most generally used for a small system is rated at 50 watts output. In rare instances a 250-watt transmitter may be required. The operating frequency usually is in the 152–162 megacycle band, the center frequency being maintained within 0.005 per cent of the assigned frequency by crystal control. The land receiver is also crystal-controlled, and for satisfactory operation on an alternate channel basis (stations two 60-kc channels, or 120 kc apart) the receiver selectivity should be about 50 or 60 decibels down at 60 kc off frequency and 85 to 100 decibels down at 120 kc off frequency. Audio output is usually a watt or two. Receivers are now universally equipped with some form of "squelch" to disable the radio receiver in the absence of a received signal and thus eliminate noise

reception during the "no signal" intervals. Both transmitter and receiver operate from 115-volt 60-cycle commercial a-c power.

The typical mobile installation is shown in Figure 2. The mobile transmitter and receiver units are generally almost identical with the land station equipment, except that the power output may be less and the primary source of power is obtained from the 6 volt car battery. Plate voltage for the receiver is obtained by a vibrator power supply, and a dynamotor is generally used for transmitter plate power.

The typical system just described has many applications. It is used by small police departments, by taxicabs, power companies, and other enterprises employing a number of mobile units. For some applications, talk back is not sufficiently important to warrant the additional expense. In such a case the mobile units may be operated on a receiving only basis, that is, vehicles would be equipped only with receivers, and only a transmitter would be required at the land station.

System for Larger Service Area

In a larger city it is found quite often that the operating point is not located in the most prominent structure in the downtown area, but is overshadowed by much taller office buildings. This, plus the much larger service area to be covered almost always makes it necessary to choose some higher location for the land station antenna. In many instances space for the radio installation is leased in the top of the tallest available office building. If there are high hills or mountains immediately adjacent to the city, the top of one of these may be selected as the radio site.

Since the transmitting and receiving equipment must be relatively close to the antenna to minimize the length of transmission line and its attendant losses, and the operating point will be at another location, some form of remote control is required. The usual arrangement makes use of a wire telephone line between the operating point and the radio transmitter-receiver site. The direction of operation of the line is reversed by the operator from the control point, through the use of a suitable control circuit.

When the land station is in the normal, or receiving condition, the audio output of the remote land receiver is fed over the line to the operating point where the level is raised by a line amplifier and fed to a loud speaker. For transmitting, the output of the microphone is amplified by a line amplifier, sent over the telephone line to the radio site and applied to the input of the land transmitter. The transfer of the wire line from receiver output to transmitter input, as well as the antenna transfer function, are under control of the aforementioned control signals actuated by the push-to-talk switch. The equipment units required at the operating point to provide remote control are customarily assembled in a console-type apparatus cabinet, called a "remote control console," which is installed on the operator's or dispatcher's desk. In addition to the features needed for local control which were previously outlined, the console probably will contain two line amplifiers, one for transmitting and one for receiving, or a single reversible amplifier to perform both functions. Provisions are made in remote control consoles, also, for monitoring the transmitter output. Usually, a small receiver tuned to the transmitter frequency is used, with some type of visual indication, often in the form of a "carrier-meter." Visual monitoring is most convenient, as it obviates the possibility of acoustical feedback from the monitoring loudspeaker into the microphone.

Another feature often found in remote control consoles is the "attention tone" signal. This is merely an audio oscillator whose output can be used to modulate the transmitter. The tone is generally sent out for a few seconds immediately preceding announcements as a means of attracting attention. This audio oscillator may also be keyed by a telegraph key if telegraphic communication is desired.

If the area to be served by the radio system is very large, and it is not possible to achieve full coverage satisfactorily with one land receiver, it may be necessary to install additional remote receivers. The outputs of these receivers can be multiplied at the operating point, or means may be provided for manual or automatic selection of the best receiver.

Systems for large cities are generally operated on a 2-frequency basis as indicated in Figure 1 with some, but not necessarily all, of the mobile units equipped for car-to-car communication. There may also be some vehicles equipped for receiving only. The mobile equipment

Figure 1. Methods of operating mobile radio telephone systems

Figure 2 (below). A typical mobile radio telephone installation

will be the same as described previously for smaller communities.

More Comprehensive Systems for Large Cities

An example of a comprehensive layout, recently engineered for the Albany, N. Y., police department is illustrated by Figure 3. This radio system illustrates the way telephone techniques may be employed to increase the flexibility and utility of conventional radio facilities.

In the Albany system, the radio land station is under control of a dispatcher-operator, who normally directs the operations of the motor car patrols. In addition, the dispatcher can give other officials at remote points access to the radio channel. Those having access are the police chief, police commissioner, chief of detectives, and the officers in charge of the six outlying precinct stations. The community of Rensselaer, across the river from Albany, is served also by the Albany police radio and the Rensselaer police headquarters has access to the radio channel. In addition, the mayor of Albany and the traffic department are provided with monitoring facilities so that they may hear all traffic carried on over the system.

In the operation of the system, picking up a handset at one of the remote locations and pressing the push-to-talk button lights a lamp on the dispatcher's key box. By depressing the associated key, the dispatcher connects the remote station to the radio facilities. Each remote station is equipped with loudspeaker monitoring equipment which is normally in operation but is automatically muted by picking up the handset. A novel feature is the "executive override" which permits the police chief, police commissioner and chief of detectives to break in on the radio channel when it has been switched by the dispatcher to one of the precinct stations.

State-Wide System

State police, large pipe-line and electric power companies and others operating fleets of vehicles on a state-wide or regional basis need mobile communication systems consisting of a number of land stations located to provide state-wide coverage and associated with a larger number of mobile units. The land stations may be connected together by a teletype or a voice-frequency wire network or both. The number of land stations required may be small if transmitting sites on high mountains are available and if maximum coverage with a minimum outlay is the only consideration. Often, however, it is desirable to have the coverage from each land station conform approximately to the boundaries of an existing administrative area. In such instances the number of land stations may be considerably increased, although the coverage requirements for each station may be correspondingly diminished. Still a third possible scheme consists in providing state-wide coverage with a few high-power stations strategically located on mountain tops, and supplementing these with low-powered installations. Traffic of a more general nature is handled by the high-power stations, and local matters are handled via the low-power stations.

Such systems are usually operated on a 2-frequency basis to permit simultaneous usage of several land stations with minimum interference. Some systems are two-way, but the so called 3-way systems illustrated in Figure 1 and similar to that employed by the Connecticut state police involving two-frequency mobile transmitters for car-to-car communication, are becoming increasingly popular. In conjunction with 3-way operation, it is often the practice to provide a second receiver at each land station location, tuned to the land station frequency. This permits monitoring of car-to-car communications by the land station and also makes possible emergency point-to-point communication between land stations.

An Example of a Statewide System

A radio system designed to give state-wide coverage with use of voice frequency wire networks has recently been placed in service for the state of New York division of state police. The radio facilities of this new system replace an earlier medium frequency a-m 1-way radio system in

Figure 3. Simplified block diagram of telephone facilities for the Albany police department mobile radio telephone system

Figure 4 (right). Simplified schematic diagram of the voice-frequency communication network for the New York state police mobile radio telephone system

Figure 5. The components of a mobile radio telephone installation

northern New York state and a 2-way f-m radio system used on Long Island.

The radio stations of the new system are grouped so as to give coverage for police cars in each of the 18 zone areas into which the state is divided for direct administrative purposes. Each radio station is directly connected for radio control purposes to one of the police locations in the zone it serves. At that point the radio circuit facilities may be connected to a wire network extending to all other police locations in the zone. The zones in the state are grouped to form six troop areas and each troop headquarters may be connected with the zone networks of its troop area. The division headquarters at Albany may also be connected to the wire network of each troop and thence to the zones throughout the state. Thus, the operation of the facilities is consistent with the organization as shown on Figure 4. At the several headquarters, zone, troop or division, a person may talk over all the facilities under his organization and control or monitor all transmissions made over such facilities.

The radio stations within each zone are normally in the receiving condition ready to pick up calls from patrol cars. By operation of a key the incoming signals may be heard over the connecting wire network at other police locations in the zone or at troop headquarters where monitoring loudspeakers are available. On instructions from Albany, any or all of the zone networks may be connected through to that point. Since the entire system is operated on a push-to-talk basis and the direction of transmission on all circuits is automatically reversed by the push-to-talk button at a control point, messages from division headquarters may be heard by all patrol cars in the state or in any portion of the state, as desired.

At each of the police locations where a radio station is controlled, a person may talk directly over the radio circuit, may let the network monitor these transmissions or may himself monitor the network while it is being used for communication between the several police locations in the zone entirely separate from any radio connection.

This radio and voice frequency wire network supplements an extensive teletype network connecting all state, and many municipal, police locations in the state.

Common Carrier Mobile Services

While many automobile operators may have a vital need for communication, the scarcity of assignable frequencies and the costs of a private system are such as to make private systems often impracticable. By obtaining service from a common carrier operating a central radio station, it becomes possible for a number of such operators to obtain the needed communication. The combination of wire and radio telephone communication circuits, using wire circuits where possible and radio circuits for connection to the mobile units, offers an opportunity to provide a logical extension of telephone service to large groups of mobile units. In addition, an arrangement of this kind at once makes it possible for the automobile operator to talk with any telephone subscriber connected to the land wire network rather than only to specific individuals at telephones which are part of the equipment in a private system.

The extensive use by the army and navy of communication with mobile units on land, sea and in the air greatly stimulated public interest in communication with mobile units. This created an unprecedented demand for mobile telephone service as a part of the facilities available for normal business operations. Following the war, a limited number of frequencies were made available in the United States in both the 30–44 megacycle band and the 152–162 megacycle band for the experimental development of a common-carrier type of mobile radio telephone communication.

Mobile Radio-Telephone Equipment

It was evident that any common carrier system would need to provide the mobile subscriber with an instrument which in use would approach closely the telephones commonly employed by the public. One of the most important additions required was a calling arrangement which when actuated by signals sent out from the central land station would ring a bell in the automobile of only the one subscriber with whom communication was desired. Since various customers were to be served on the same channel, it was out of the question to employ the "voice-loudspeaker calling" generally in use on private mobile systems. A selective signaling system had been developed for use on small coastal ships and had proved to be extremely reliable. This was adapted for mobile service as the most readily available at that time.

Selective signaling of mobile subscribers is accomplished by means of a selective-signaling oscillator at the control point and a selector in the mobile unit. The selective-signaling oscillator provides a code consisting of a series of alternate pulses of 600 and 1,500 cycles which are transmitted at a uniform rate under control of a standard telephone dial or sender at the toll switchboard. Selective circuits in the selector of the mobile unit alternately respond to the 600 and 1,500-cycle tones and operate a stepping relay which actuates a Gill selector to rotate its contact wheel. Five code pins are placed in the contact wheel in positions corresponding to the five digits which comprise the telephone number of the particular selector. When any digit is dialed the contact wheels of all mobile stations receiving the transmission will advance a number of steps corresponding to the digit dialed. Only those wheels, however, that have a pin at the point of advancement corresponding to the digit dialed will hold, and the remainder will return to normal. Successive dialing of digits causes all selectors to again advance. However, only the selector which progressively advances on all five digits causes a bell and lamp to operate in the automobile.

Other modifications made in the commercially available radio equipment were to improve reliability, increase safety and provide for ease in maintenance. Although the equipment in the automobile was otherwise much the same as described previously for private systems, these changes and the use of a hang-up type handset made the subscriber equipment as much like one commonly employed as could be devised without extensive development. The one unusual feature which remained was the push-to-talk switch in the handle of the handset. Developments aimed toward the ultimate elimination of the push-to-talk switch are now under way.

The adaptation and use of mobile radio-telephone units has given added knowl-

Table I. Technical Characteristics of Mobile Equipment Recommended for Bell System General Mobile Telephone Service

Number	Item	Highway Service	Urban Service	Notes
1.	Frequency range			
	transmitting, megacycles	42–44	152–162	
	receiving, megacycles	30–40	152–162	
2.	Maximum frequency tolerance (−20° to +55° C), per cent	0.01	0.005	
3.	Type of modulation	phase	phase	
4.	Predistortion (referred to f-m characteristic) decibels per octave	6	6	
5.	100 per cent modulation swing, kilocycles	±11 (±7.3 radians)	±15 (±10 radians)	
6.	Audio band transmitted, cycles per second (see Item 25)	300 to 3,000	300 to 3,000	
7.	Maximum radio band width, kilocycles (tolerance plus modulation)	40	60	
8.	Output power, watts	20–40	15–35	
9.	Maximum transmitter spurious radiation	Ultimate—0.1 microwatt (equals 85 decibels below present carrier power) for frequencies within 20 per cent each side of the carrier. One microwatt (equals about 75 decibels below present carrier power) at all other frequencies. Temporarily acceptable—3 microwatts (equals about 70 decibels below present carrier power)		
10.	Radio transmitter input impedance, ohms	40	40	
11.	Radio transmitter output impedance	Suitable to feed 70-ohm transmission line with standing wave ratio up to two		
12.	Maximum residual transmitter noise modulation	The measured residual transmitter noise should be 47 decibels below the level of a 1,000-cycle sine wave tone which modulates the transmitter the full radian swing.		See Note Following Item 21
13.	Receiver sensitivity			See Items 17 and 18
14.	Receiver acceptance band, kilocycles (6 decibels down limits)	Ultimate—±10 to ±15. Temporarily acceptable: ±10 to ±25	Ultimate—±20 to ±25. Temporarily acceptable: ±20 to ±50	
15.	Receiver selectivity	Ultimate—85 decibels, adjacent mid-channel. Temporarily acceptable: 60 decibels, alternate mid-channel	Ultimate—85 decibels, adjacent mid-channel. Temporarily acceptable: 60 decibels, alternate mid-channel	
16.	Receiver spurious responses	Ultimate—85 decibels down. Temporarily acceptable: 70 decibels down	Ultimate—85 decibels down. Temporarily acceptable: 70 decibels down	
17.	Limiter effectiveness, decibels	30	30	
18.	Signal input for complete limiting, microvolts	5	5	
19.	Maximum "squelch" sensitivity, microvolt (adjustable inside equipment over 25 decibels range)	1	1	
20.	Radio receiver noise figure, decibels	12	8	
21.	Maximum residual receiver noise (car engine operating)	The measured residual receiver noise (car engine operating) should be at least 34 decibels (ultimately 50 decibels) below the level of a 1,000-cycle sine wave tone which modulates the test radio frequency signal, the full radian swing which is given in Item 5.		The noise should be measured in a manner which takes account of its interfering effect on a telephone circuit. This can be done by using a meter having a flat transmission characteristic and dynamic characteristics similar to the standard volume indicators* (a volume indicator or a noise meter may be used) in combination with a frequency weighting network. Figure 9 shows the characteristic of the weighting network commonly used in telephone work. Successive measurements are made first with the test radio frequency signal modulated with 1,000-cycle tone then with no modulation. In measuring residual noise in radio transmitters the same general method may be applied by using a radio receiver with very low residual noise to demodulate the transmitter signal.
22.	Radio receiver de-emphasis (referred to f-m characteristic) decibels per octave	6	6	
23.	Audio output impedance, ohms	600	600	
24.	Radio receiver output power, milliwatts	250	250	This assumes loudspeaker operation is not required. 250 m.w. will operate a selector set (see Item 26). The handset receiver requires 10 m.w.
25.	Audio characteristic (with 100 per cent modulation) of transmitters or receivers, cycles per second	1,000, reference 250, 0 to −4 decibels 500 to 2,000 +1 to −3 decibels 2,000 to 3,200 0 to −4 decibels	1,000, reference 250, 0 to −4 decibels 500 to 2,000 +1 to −3 decibels 2,000 to 3,200 0 to −4 decibels	The characteristic of a transmitter or a receiver is specified in terms of its departure from the ideal 6 decibels per octave pre-emphasis or de-emphasis, respectively.

26. Selective signaling. The selective signal receiving unit (selector set) must respond to the 2-tone audio-frequency selective signaling code transmitted by the land station.

The transmitted code consists of a series of pulses of two tones, 600 and 1,500 cycles per second, which are transmitted alternately at a uniform rate of 8 to 11 per second. The tones are transmitted successively without interruption and all pulses are of equal length (0.09 to 0.125 second.)

The current code plan for 2-way general mobile service** is based on a 23 pulse series, that is, a total of 23 pulses closes a local signal contact in the selector set. Coding is accomplished by breaking the sequence of 23 pulses into five groups, 2 to 10 pulses per group. Each of these groups corresponds to a digit (digit "0" corresponds to 10 pulses), in a 5 digit code number the sum of whose digits is 23. The digit "1" is used only as a "clearing" or preparatory signal to restore all selectors to their rest position and is therefore not available for use in any code number. One pulse or digit "1", is normally transmitted immediately preceding the transmission of a code number to make sure that all selectors start from the rest position. It is also transmitted again after the code number has been transmitted to release the called selector and silence the bell after a reasonable ringing interval.

Table I (continued). Technical Characteristics of Mobile Equipment Recommended for Bell System General Mobile Telephone Service

The local signal circuits associated with the selector set should provide a bell of suitable audibility and a lock-in lamp signal. The bell circuit should be arranged to remain operated (bell ringing) as long as the selector contact is closed. The lamp circuit should operate when the selector contact closes and remain operated (lamp lighted) until the local circuit is restored by the operation of a release button or contact.***

Proper utilization of the available code numbers without conflict necessitates centralized administration of code assignments. Code number assignments for general mobile telephone service must be obtained from the local telephone company.

27. Full operation of radio transmitter required within 300 milliseconds after "push-to-talk" button in hand set is depressed.
28. Nominal battery voltages either 6 or 12 volts. All characteristics should be met with battery terminal voltages between 5.7 and 7.5 volts for 6-volt system and between 11.4 and 15 volts for 12-volt system. Equipment should tolerate for ten minutes without permanent damage voltages of 5.0 or 8.5 for the 6-volt system and of 10 or 17 volts for the 12-volt system. Equipment should tolerate one second reductions of power supply to one-third of nominal voltages.
29. The equipment should operate satisfactorily with ambient temperatures ranging from −40 to +55 degrees centigrade (−40 to +149 degrees Fahrenheit.)
30. The voice frequency control unit used for Bell System installations will generally include, as mentioned in Item 27, a push-to-talk hand set, (Western Electric Company *F3WW*) equipped with a carbon button-type transmitter unit and a telephone-type receiver unit and having a 5-conductor cord. (In some few cases a radio-type microphone such as the condenser type and a loudspeaker may be used on a push-to-talk basis.) The frequency characteristics of the hand set (or equivalent talking and listening apparatus) should be such as to utilize efficiently the voice frequency band specified in Item 6. The control unit should also include, as indicated under Item 26, a lamp and signal bell to indicate incoming calls and a power control switch and associated indicating lamp.

* American Standards Association *Standard* C16.5, 1942.

** One-way signaling service will make use of codes totaling 23 pulses. The first digit of such code numbers will always be "9."

*** The Western Electric Company *106A* Selector Set (distributed through Graybar Electric Company) is designed to operate with the selective signaling system described before. It has a second local circuit contact closed by a total of 25 pulses. A minimum of 100 milliwatts at 600 cycles and 1,500 cycles is required to operate the number *106A* Selector Set. Its input circuit includes a transformer with 2-ohm and 500-ohm taps. A 100–250 volts direct current supply capable of delivering 2 milliamperes is required (this is usually obtained from the receiver power supply).

edge and experience in the desirable characteristics for these units. A table of the most recent views concerning the desirable electrical characteristics is given in Table I. The components of a mobile installation specifically designed for this service and having the desirable characteristics are shown in Figure 5.

Land Station Radio-Telephone Equipment

As in the case of mobile units, in providing land station installations the process also was one of adapting available equipment to new conditions. Special automatic monitoring means were added to the land station transmitters. A relay was added to the land station receivers which would operate when the "squelch" of the receiver indicated the reception of a signal. This relay in turn sends a control signal over a wire circuit which finally actuates a call-indicating lamp in the toll switchboard.

Control Terminal Equipment

The control terminal is in many respects the counterpart of the remote control console described previously. However, it is fully automatic and furthermore provides receiver selection, testing facilities, and alarm circuits for the radio units of the system. This control terminal is a simplification of the type which has been in use for a number of years on the radio-telephone circuits for coastal and harbor vessels. The conventional hybrid coil and the vogad (voice-operated gain-adjusting device) are the most essential features of the control terminal as it is possible by their use to combine effectively a transmitting circuit and a receiving circuit into a 2-way talking circuit for connection as another line into a toll switchboard of the telephone network. Figure 6 indicates in schematic form how the several parts of the common-carrier type of mobile radio-telephone system are integrated into a single operating whole.

Extent of Development

Systems such as have been described for common-carrier use have been put into operation at a number of places throughout the United States since the first one in St. Louis, Mo., was activated on June 17, 1946. The map of Figure 7

Figure 6. Block diagram showing principal components of a general mobile telephone system

indicates the places in the United States and Canada where one or more such systems were furnishing service at the beginning of 1948. Not shown by the map is the fact that there were then 102 land stations in operation providing service to about 4,000 mobile units.

Coverage

Marginal signals, requiring repetition, are probably less acceptable to common-carrier subscribers than to the users of private mobile systems. The radius of acceptable coverage of an urban mobile system (152–162 megacycle band) is in the order of 15 to 30 miles, depending upon the height of the land transmitting antenna and the terrain and noise level prevailing in the area. By astute selection of land receiver locations based on detailed field surveys, equal coverage areas for both directions of transmission are usually provided. Difficulty may sometimes be encountered in suburban areas where a high noise level is encountered at the extreme range of the land transmitter coverage area; however, this has not so far been a troublesome problem. In general, the minimum acceptable field strength for reception by a mobile unit in a high-noise area is regarded to be about 100 microvolts per meter. In reasonably quiet areas, a field strength of perhaps 30 microvolts per meter is considered to be acceptable. In order to produce a field strength of at least this magnitude out to more than 15 miles, with reasonable antenna heights, a 250-watt transmitter is usually required. Ignition noise, diathermy and other man-made noises are very troublesome in the highway frequency band (30–44 megacycle band). Likewise, long range interfering signals produce annoyance on these frequencies particularly in magnetically disturbed years when high maximum usable frequencies obtain on paths from 1,000 to 3,000 miles in length. Zone allocation of frequencies for exclusive use in areas not over about 1,000 miles in greatest dimension has proved helpful in mitigating this difficulty. Experience has shown that if complete coverage is to be obtained along a highway with land stations not exceeding 250 watts in power the stations will need to be placed every 50 to 100 miles on the average. It is usually desirable to employ land receivers at much closer intervals to make up for the lower powered mobile units.

Multiple Channel Problems

In order to provide service to more than a very few of the automobiles in a large city area, more than a single radio channel must be employed. As the service becomes more commonplace the expansion will doubtless be considerable. Several of the cities in the United States already have three channels in the urban band and one in the highway band in successful operation. Where the frequency difference is considerable, as between urban and highway frequencies, the problems which arise because of the close physical proximity of antennas can usually be cared for by the conventional use of resonant coaxial line filters.

There are, however, situations which arise, as between channels spaced 60 or 120 kc apart in the 152–162 megacycle band which cannot readily be attacked by simple selectivity means. Briefly stated, the primary problems encountered in attempting to operate radio systems closely spaced in frequency and in location are these:

Insufficient receiver selectivity.

Intermodulation between several land transmitters in close proximity.

Intermodulation in non-linear stages of land and mobile receivers.

These problems may best be illustrated by describing the difficulties encountered in a typical multichannel installation in Philadelphia, Pa. A pictorial representation of the Philadelphia case is shown in Figure 8. The Yellow Cab Company radio installation and the first telephone company installation were operating on frequencies which, for purposes of ready reference, are called Channel 5 (152.27 megacycles) and Channel 11 (152.63 megacycles) respectively. These radio systems operated satisfactorily without interference. However, when the telephone company Channel 9 (152.51 mega-

Figure 7. Extent of development of general mobile telephone service

Figure 8 (left). Locations of land stations involved in Philadelphia interference difficulties

Figure 9. Characteristics of frequency weighting network

cycles) installation was placed in operation at a later date, serious interference was noted in the taxicab receivers. Transmitter intermodulation products resulting from the simultaneous operation of Channels 11 and 9 had been anticipated, and a special balancing circuit designed by Bell Telephone Laboratories had been installed to reduce these products to tolerable limits. This balancing circuit, in effect, introduces a voltage from one transmitter into the other in opposite phase and equal in magnitude to the voltage introduced through the mutual coupling of the antennas. The voltages which produce intermodulation are thus canceled. Tests indicated that this circuit was operating satisfactorily, and further investigation disclosed that the interference was caused by serious overloading of the vacuum tubes in the radio-frequency stages of the taxicab company land station receiver.

In the taxi system, the same frequency was used initially for both directions of transmission. Since the land receiver was in the downtown area, it was exposed to strong signals from the telephone company land transmitters. The receiver was also required to be sensitive to weak signals from distant vehicles. The telephone company has avoided this, and a number of other problems, by using one frequency for each direction of transmission. The two frequencies are spaced about five megacycles apart which gives sufficient separation to obtain effective use of selective circuits. This practice has proved to be necessary if serious interference is to be avoided in metropolitan areas, and the taxicab company has now converted its system to 2-frequency operation.

With 2-frequency operation of the taxi system the land station receiver was, of course, no longer subject to overloading and no interference was encountered. However, when the mobile units came in close proximity to the location of the telephone company land transmitters, receiver overloading occurred. Under this condition the combination of strong signals from Channels 9 and 11 produced an interfering signal in the mobile receiver itself. To overcome this interference an automatic gain control can be introduced in the radio-frequency stages of the receiver to reduce the receiver gain when such high-level signals are encountered. This gain control prevents interference when the taxi land station is operating and when the taxi is in the vicinity of the telephone company stations.

A very selective receiver would be required for interference-free operation on channels which are spaced 60 or 120 kc apart. Since frequency-modulated receivers are used, interference between two channels 60 kc apart is not experienced while both channels are operating if the receivers have moderate selectivity. However, a so-called "false busy" indication may be encountered when a mobile user, listening to determine if the channel is idle preparatory to placing a call, hears interference from an operating adjacent channel and concludes that his own channel is in use. This interference is overcome by operating adjacent-channel transmitters simultaneously. The unmodulated signal of the idle channel thus effectively reduces the gain of the mobile receiver and eliminates the interfering signal caused by the busy channel. It is necessary, of course, that all transmitters be in close proximity so that approximately equal signal strengths are received throughout the service area.

Conclusion

The development of mobile radio for telephonic communication with automobiles has extended over almost three decades. Much has been accomplished but much remains for the future. Already the task of providing more and better facilities has introduced new problems for the engineer. The fusion of wire telephone and radio techniques has created a co-ordinated system with great possibilities.

Discussion

David Talley (International Standard Electric Corporation, New York, N. Y.): In this paper on Mobile Radio, Austin Bailey has done a very commendable job in tracing the developments of the past 25 years in this important field and condensing the more important points into a form suitable for presentation at this meeting. In accomplishing this difficult task, it is felt that possibly several important considerations may have been omitted, other items not fully covered due to limitation on length of the text and probably some points may require additional exemplification. It is the object of my discussion to briefly explore these matters and to possibly further clarify the whole subject of mobile radio communications.

In tracing the history of mobile radio communications developments, Bailey quite properly associates it with the expansion of the police radio systems. Due credit also should be given to E. H. Armstrong's development of frequency modulation (f-m), which together with the advent of suitable vacuum tubes and circuit components for the very high frequencies—30 to 300 megacycles—have made possible the present growth of mobile radio. It may be in order at this point to inject a few statistics to show how quickly radio equipment can be outmoded by advances in the art. In 1940, Federal Communications Commission data listed over 1,250 police radio systems in the United States employing amplitude modulation, mainly in the 1,600–2,000 kilocycle band. Only a few systems were f-m in the 30–44 megacycle range. Today, almost every police system has changed over to f-m operations in the 30–44 or 152–162 megacycle bands, as noted by Bailey. Also, it is significant to observe that power utilities, taxicabs, telephone companies and other users now outnumber the police in the applications of mobile radio, as further discussed later.

The impetus of the recent war to mobile radio is touched upon only too lightly. When it is recalled that every American tank and most other military vehicles were equipped with f-m mobile radio sets operating in the 22–40 megacycle region and that thousands of men became familar with the operation of these mobile sets and the quasi-line-of-sight range of the very high frequency band, one can more readily comprehend the present great interest in the mobile radio services. Wartime research and development, especially in the design of vacuum tubes and components suitable for the very high frequencies, have been instrumental in making it possible at present for manufacturers to supply large quantities of mobile radio equipment at moderate costs.

In his paragraph on Modern Mobile Radiotelephone, Bailey briefly referred to the present trend for mobile radio systems to move from 30–44 to 152–162 megacycles and higher frequencies due to the overcrowded conditions on 30–44 megacycles and because of less noise, shorter automobile antenna heights required for the higher frequencies, and so forth. It should be noted that frequencies in the 30–44 megacycle range will cover greater distances than 152–162 megacycle transmissions where the radio path is over "good soil," that is, earth having high conductivity such as clay, marsh, loam, or swamp land. For transmission over "poor soil" or low conductivity, that is, land consisting largely of rocks, gravel or sand, the maximum communication distances are about the same for both these frequency bands over level terrain.

Shadow losses due to intervening objects in the radio path such as hills, ridges, and buildings are much greater for 152–162 megacycle transmissions than 30–44 megacycles. On the other hand, multiple reflections from buildings in cities are more pronounced on 152–162 megacycles as compared to the lower frequency band. This tends to fill in the deep shadows in the radio path at street level which makes possible uninterrupted communications with moving motor vehicles even along the streets of New York or other large cities. It is necessary, for this condition, that the land station transmitting antenna be located as high as possible with respect to surrounding buildings. In suburban areas, especially in locations where "good soil" conditions exist (as defined before) greater distances can be achieved on the 30–44 megacycle frequencies. This increase in range may amount to as much as 50 per cent under very good conditions. The foregoing factors should be carefully considered when it is possible to have a choice of frequency allocations for a particular installation.

It may be of interest that the writer has talked from mobile radio equipped automobile driving through the streets of Buenos Aires, Argentina to another car in the vicinity of Philadelphia in connection with certain tests made in June, 1947. Telephone calls also have been made from a car of the Mutual Telephone Company in Honolulu, T.H., to different cities in the United States during the past year. The Cuban Telephone Company is installing mobile radio service in Havana and the Compaia Telefónica y Telegráfica Mexicana, an associate of the International Telephone and Telegraph Corporation, is now experimenting with urban mobile service in Mexico City. The international aspect of mobile radio communications is now a well-established fact.

In the section on Typical Present-day Mobile System for Small Areas in the United States, Bailey has very ably described the low-power mobile radio system now usually installed by small police departments, power companies, and taxicab dispatching. The average land station transmitter for these systems generally is rated at less than 50 watts output for operation on the 152–162 megacycle band. Remote control arrangements normally are available so that the equipment can be installed as near the antenna as possible to take advantage of short antenna connecting cable (100 feet or less) thereby reducing the power loss in the antenna transmission line. The remote control unit, which usually comprises loudspeaker, handset, and control keys, ordinarily is installed in the dispatcher's office in the same building. For remote control operations from a more distant point, leased telephone line facilities can be employed.

With reference to the section on Mobile Radiotelephone Equipment, Bailey only mentions and describes the pulse count type of selective signaling equipment (known as the Western Electric Number *106 A* selector set) which is in current use by the Bell Telephone System. This particular selector has a capacity of 2,030 code combinations on a five-digit basis but it is very expensive; costing about $300 each which is an appreciable proportion of the average cost of the mobile radio set in the motor vehicle. A different type of signaling system utilizing tuned reeds has been recently developed which will probably cost less than one-third that of the pulse count selector variety. With four reeds, it is possible to obtain 10,000 numbers on a four-digit basis which should provide adequate numbers for future expansion of the urban and highway mobile services. In addition, the Selecto-Call feature also employing reeds, used by one manufacturer of mobile radio equipment, makes it possible to lock-out all but the particular car that has been called.

The elimination of the push-to-talk switch in the handle of the handset has been accomplished on mobile radio installations in certain railroad pullman cars of the Baltimore and Ohio and Pennsylvania Railroads, on their New York—Washington route. This has been possible primarily because separate transmitting and receiving antennas were installed, one at each end of the railroad car. Space considerations do not permit this on motor vehicles so that some other method is required for full duplex operation as on wire line telephones. This feature, although desirable, is not so important for private mobile systems not connected to the telephone plant.

One other point concerning mobile radio equipment, not mentioned in Bailey's paper, should be of prime interest. This is the high current drain on the motor vehicle's storage battery by present-day mobile equipment. For example, the average 25–30 watt 152–162 megacycle mobile transmitter takes over 40 amperes and the 50 watt 30–44 megacycle transmitter requires as much as 70 amperes from the 6-volt car battery during transmissions. The mobile receiver draws from 7 to 10 or more amperes continuously. It is usually necessary, for optimum service, that the standard battery and charging generator in the car be replaced by heavy duty types. This additional expense may make mobile radio service uneconomical for some private system users. The trend of development by radio manufacturers is towards lower power mobile sets requiring battery currents during transmissions of 20 amperes or less. Mobile units rated at 7–10 watts output power in the 152–162 megacycle band are now available which have low-current requirements, smaller dimensions and yet can cover an appreciable amount of the service area as the higher power equipment. The use of vibrator power supplies instead of dynamotors, availability of improved vacuum tubes and smaller components have made possible the manufacture of these efficient low-power mobile sets. With reduced cost of mobile equipment, it is felt that many more industrial and private users will find it economical to install mobile radio systems, particularly if no additional expenses, such as heavy duty car batteries and generators, are required.

Referring to the paragraph on Control Terminal Equipment, a few more words on the necessity of receiver selection may be in order. When several remote receivers are utilized to cover the service area, the re-

ceiver nearest to the calling mobile station generally affords the best signal-to-noise output to the control terminal. The other remote receivers contribute varying amounts of noise which adversely affect the over-all performance of the circuit. As a result, manual selection of the best receiver has been necessary in the past to exclude the other receivers. With the increasing use of lower power transmitters, additional remote receivers may be needed for adequate coverage purposes. The development of automatic selection circuits for land receivers also will greatly simplify the operation of mobile systems utilizing a number of remote receivers. Since it is not possible to assign a very high frequency channel for the exclusive use of each private mobile radio system operating in a locality, sharing of channels is necessary. It is not uncommon, therefore, for two, three or more taxicab companies in a town or urban areas to operate on the same channel. The resultant interference and obvious operating difficulties may impair the economic value of mobile radio dispatch service to the taxicab industry. One possible expediency pending further technical developments that may afford multichannel operations on a particular frequency allocation, might be to combine taxicab dispatching operations at one central transmitting-receiving station in each locality. With the continued growth of the mobile service, it is probable that subscribers to common carrier mobile telephone service may become the majority of users and a mobile telephone in every automobile is not a too remote possibility.

It is hoped that this discussion of Bailey's excellent paper on mobile radio will serve to further emphasize the many advancements in this important communication service since World War II. Although no one can foretell the future extent or the ultimate form of mobile communications, possibly the following anecdote attributed to Doctor Jewett, the famous scientist and former head of the Bell Telephone Laboratories, may indicate the objective. When Doctor Jewett once was asked to define the ultimate objective of communications, he replied to the effect that when you could take out of your pocket an instrument the size of a watch, dial the number of a particular person anywhere in the world and if he did not answer, you knew he was dead; that is the ultimate of communications.

Ten Years Performance of Lightning-Resistant Wood-Pole Transmission Lines

R. M. SCHAHFER
MEMBER AIEE

W. H. KNUTZ
MEMBER AIEE

OUR INTEREST in improving the lightning performance of transmission lines was accentuated several years ago when we were designing and constructing some additions to our 132-kv steel tower lines.

The service record of these 132-kv lines, compared with the records of similar lines of other utilities in adjoining areas, indicated the need of improvements in our lines. Comparisons were made of construction, type and extent of shielding, exposure, type and number of insulators, use of arcing horns and grading shields, line configuration and spacing, prevailing winds, storm direction severity and frequency, ground resistance values and conductor clearances to towers. All lines studied had reasonably good shielding and were similar in other construction features. The only outstanding difference found was that the ground resistance of our lines was noticeably higher. This comparison, which theoretical calculations also substantiated, indicated that we could improve the performance of our lines by lowering our ground resistance.

Each type of tower was studied as to its minimum flashover clearance, and the resistance of that tower was lowered to a value which was computed to make the tower reasonably free from lightning flashover. Outages from lightning were reduced about 81 per cent.

These results were so encouraging that we decided to incorporate shielding, grounding, and co-ordination of insulation in our 33- and 69-kv wood-pole transmission lines.

Paper 49-126, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted December 3, 1947; made available for printing March 11, 1948.

R. M. SCHAHFER is mechanical and electrical engineer, W. H. KNUTZ is special engineer, both of the Northern Indiana Public Service Company, Hammond, Ind.

Previous Operating History of 33-Kv Lines

A study was made of the lightning performance of all 33-kv overhead lines of the Northern Indiana Public Service Company for the years 1932 to 1938 inclusive. The year 1932 was chosen because this was the year in which adequate records were available. The year 1938 was chosen because it was the last year prior to our modern lightning-resistant wood-pole transmission line design.

These lines are located in northern Indiana in the area extending from the Illinois state line to the Ohio state line, and from the Michigan state line south about 75 miles. Therefore, a wide geographic area, subject to varied storm hazards is served. Figure 1 shows typical examples of our unimproved lines. Like all systems which have grown up over a period of years, they include many types of construction which have been popular in the decade preceding 1932.

The outages per 100 miles per year for this entire system for the period 1932 to 1938 inclusive are:

Lightning	40.1
Other Outages	31.7

Operating History of Lines with All Wood and Porcelain Insulation

At one time there was a prevailing belief that by means of wood insulation, conductors could be separated sufficiently to prevent lightning flashovers. Prior to 1930, three lines were constructed wherein an attempt was made to insulate the structure so highly that no flashover would occur and that the force of the lightning would be dissipated in attenuation along the transmission line. These three lines traverse some 71 miles of the state of Indiana and are in two different geographic areas which are not subject to the same storms.

The first of these lines, Figure 2, was a 69-kv line, 45 miles long, extending from Plymouth to Goshen, Ind. It was of wishbone configuration using double plank arms. Six insulators were used on the top phase, five on the middle, and four on the bottom phase. Conductors were widely separated. All guys included wood insulators. Care was taken to see that ample clearance was maintained to all distribution circuits. There were no shielding wire or pole grounds. The failure of this line to withstand lightning was so noticeable that every possible weak spot in the insulation such as guy points and distribution attachments were reinforced with greater insulation in two successive investigations, but with no appreciable improvement in operating results. In eight and one-half years, we experienced 217 outages on this line. Lightning caused 163 of these outages, which is 48.3 outages per 100 miles per year. A second 69-kv line, extending from Monticello to Oakdale, Ind., a length of 7.8 miles, was similar in all repects to the previously described line as originally constructed, except that it is in a different geographic area. In 16 years, this line tripped out from lightning 46 times, which is 36.8 outages per 100 miles per year.

The insulation of these two lines was sufficiently high to cause transformer failures in their 69-kv winding even though the transformers were protected by a conventionally located standard lightning arrester. This trouble was corrected by reducing the insulation of the line in a few spans immediately adjacent to each substation.

A third 69-kv line, shown in Figure 3, extended from Oakdale to Lafayette, Ind., a distance of 18.4 miles. Each conductor was supported by five insula-

Figure 1 (left). Types of transmission lines constructed prior to 1938

Figure 2. Wood insulated line, 69-kv wish-bone type

tors and was spaced for future 132-kv operation. The line was of *H* frame construction. A small portion of the cross-arm was by-passed by a steel brace, but sufficient wood remained unby-passed to make these structures equivalent in insulating value to the wishbone-type lines previously described. There were no static wire or pole grounds. In 12 years, this line had 218 outages. Lightning caused 125 outages, or 56.7 outages per 100 miles per year.

Summarizing the operation of these three highly insulated lines, none of which employed a static wire, we find that the outages per 100 miles per year are:

Lightning	48.9
All other	29.6

These results are no better and in fact are worse than the record of our entire 33-kv system, and gave little hope that any such type of construction would be successful.

Operating History of 69-Kv Line with Shielding Wire

A 69-kv line, 45.1 miles long, extends from Oakdale to Kentland, Ind. This is in the same geographic area as the last two lines described in the preceding section,—all three lines being connected to the same bus at the Oakdale substation. Hence, all three lines have more or less identical storm exposures.

This line, shown in Figure 4, is constructed on two 10-foot arms using steel braces. Five insulators are used. A shielding wire is supported on a steel bayonet. The shielding wire is grounded at each pole, the grounding-down lead being placed on the surface of the pole. No attempt was made to secure low-ground resistance values, consequently many are higher than they should be. The use of steel braces, steel bayonets, and the position of the down lead greatly reduce the impulse flashover of the line. The performance of this line was much better than the highly insulated lines described previously. The outages per 100 miles per year for the period 1932 to 1947 inclusive are:

Lightning	6.5
All other	21.1

This line is classified as semimodern because it does not take full possible advantage of the wood insulation. Our theoretical studies and our analysis of operating records of the foregoing enabled us to develop the transmission lines we are now building.

Operating History of Modern Design

We classify as modern design those transmission lines which are shielded by an overhead ground wire so located as to provide a cone of protection of approximately 45 degrees. Wherever possible, hardware, which would reduce the value of wood insulation, is eliminated. The shielding wire is grounded at each structure. The grounding down lead is set out from the pole. A high insulating value with all flashover paths co-ordinated is incorporated in designs. We classify also as modern design, those transmission lines which are constructed with high insulation values and without a shielding wire, where such lines are located so that they are shielded by other structures with the same 45 degree cone of protection. Lines constructed parallel to, and under an existing 132-kv tower

Figure 6 (right center). 33-kv, shielded and grounded construction

Figure 7. 69-kv wishbone line, improved by shielding and grounding

line are examples of such type of shielding.

Since 1938, all new and all alterations to existing 33-kv and 69-kv wood-pole lines have incorporated the modern shielding, grounding, and high-impulse insulation-value features.

The first line so built extended from Goshen to Angola, Ind., a distance of 50.8 miles. This line operates at 33-kv. A short section, 0.7 mile long was added at a later date. This line was built with two 10-foot arms and wood braces. One section of this line was built with four suspension insulators for future 69-kv operation.

Another section has two suspension insulators and a third section employs pin-type insulators. Grounds were driven to approximately 5.5 ohms, except for a section about two miles in length where some resistances were over 100 ohms and could not be reasonably reduced. Figures 5 and 6 show some construction features of these lines, later designated as circuits *A* and *B*.

The second line to employ the features of our modern design was the modernization of the previously described wood and porcelain insulated 69-kv line which extended from Plymouth to Goshen. The record of this 45-mile line, previous to modernization, showed 48.3 outages per 100 miles per year from lightning. A shielding wire was installed and grounded at each structure. Maximum ground resistance at each structure was limited to 5.5 ohms. Insulators were rearranged so that the conductors were supported with 4, 5 and 6 units from top to bottom respectively. This rearranging of the insulators improved the impulse insulation of the line and also increased conductor spacing, so that a previously serious dancing conductor condition has been practically eliminated. After modernization, from the years 1939 to 1947, lightning has caused only three outages, which is 0.8 outage per 100 miles per year. This modernized line is shown in Figure 7, later designated as circuit *C*.

A third line was constructed in 1940 using a simplified self-supporting arm design. This line operates at 33 kv. A shielding wire was installed and each structure grounded to about 20 ohms. This type of line will be described in greater detail later. This line is designated as circuit *D*.

The operating record of these four modern lines is shown in Table I.

While many other lines have been built or altered to embody our modern design features, their operating record is not included in the foregoing summary. The lines included are modern from terminal to terminal, and no guessing or estimating is necessary to analyze their performance. At the time this analysis was started, all other lines were intermingled with some sections of older designs. Hence, to include them in this summary would involve some estimating and create a question as to whether operations were being included or excluded fairly.

Geographic Location of Lines Investigated

Figure 8 shows the location of the various lines discussed previously. Thus, it will be readily apparent that the lines cover a wide geographic area, across the state of Indiana, and are not subject to any restricted storm exposure.

Modern Design Features

The 69-kv wishbone line previously described employed double plank arms and special hardware. The arms were difficult to install, mechanical safety factors exceeded requirements, and costs were high. The 69-kv semimodern line did not take full advantage of the wood insulation. Both this and our first modern lines have an unbalanced load on one crossarm. The wishbone line does result in better mechanical balance. As a result of these comparisons, a simplified self-braced arm structure was developed. This is known as our type *F* single circuit construction. This structure is shown in Figure 9. The

Calculation of insulation level and required ground resistance

dimensions are given in Figure 10. Arms are offset from center and coupled together at one end by means of an inexpensive U plate. This results in a more equal arm loading and eliminates the distortion frequently encountered when an arm supports a conductor on one end and none on the other. While this construction results in less clearance to the down-lead ground wire of the top conductor than for others, a study of the impulse insulation value of the various conductors, when corrected for the effect of coupling factor with their relationship to the shielding wire, will show this to be a well balanced structure electrically as well as mechanically.

The shielding wire shields all conductors in a cone of protection of approximately 45 degrees or less. This value was obtained as a good compromise considering the operating record expected and obtained, the cost of greater or less length of pole, and the amount of pole needed above the crossarm so that this path of flashover would not weaken the impulse value of the structure. The shielding wire is grounded at each pole. The down lead is extended out from the pole by means of extended neutral stud bolts, and is offset transversely from the pole center line to equalize the flashover values of the three phases. Steel stud bolts are used rather than wood extensions because of permanency, but being steel, must be located so as not to reduce the insulating value of the structure. The location of one extended stud bolt at the shielding wire attachment also supports the weight of the down lead and thus minimizes the probability of establishing a fatigue point in the shielding wire. If the down lead wire were to lay on the surface of the pole and thus eliminate all value of the wood insulation of the pole, then the impulse strength of the entire structure would be reduced to about one-half of the structure we are now using. From published data on the expectancy of lightning strokes to exceed any given value, we can predict that a structure designed to protect

against lightning strokes of 100,000 amperes will have only about one-sixth of the lightning flashovers that would occur on a structure designed to protect against 50,000 amperes.

It is to be noted that provision is made for distribution underbuild. When the distribution is single phase the arm which supports it is coupled to the lower transmission arm by means of another U plate. For 3-phase underbuild an additional 2-pin arm is installed below the arm supporting the single distribution conductor. The shielding wire is used as a neutral for the 12.5-kv or 4-kv distribution system.

This simplified structure incorporates all the lightning resistant features of shielded and grounded lines constructed with two arms and wood braces. The method of determining flashover values and desired ground resistance is illustrated in Figure 11. The air gaps are from conductors to grounded down lead or shielding wire by one of three paths.

1. Direct from conductor to ground wire or down lead wire by air,
2. Across porcelain, arm, and pole to ground wire, or
3. Across porcelain, arm, and by air to the down lead wire.

Flashover values are calculated from the following equation by L. V. Bewley.[1]

$$V=(1-C_n)aR'I+e$$

Where

V = voltage across insulation
C_n = coupling factor
a = crest factor
R' = effective resistance
I = lightning current
e = instantaneous normal frequency voltage

Values are based on $1^1/_2\times40$ positive wave with time to flashover t taken at a wave front f of two microseconds. Span length T is reduced to microseconds.

It will be seen that our design provides a flashover path directly from conductor to down lead wire less than the other paths. This is desirable so that any flashover which may occur will follow this path, and arm and pole splintering will thus be avoided. Although the insulation of each conductor is different, each when related to coupling factor, which takes in account the spacing of the conductor relative to the shielding wire, requires about the same ground resistance for the same lightning protection. In calculating the flashover values of the wood paths, we reduced values of wood 30 per cent to allow for the effect of rain.

A 2-circuit structure similar to the single circuit structure is shown in Figure 12. This is known as our Type *F2* double circuit construction. The dimensions are given in Figure 13. For this structure the arms are centered on the pole. Two coupled arms are installed on one side of the pole and two on the other side. When double arms are needed, it is necessary to revert to a structure with three horizontal double arms. The flashover values and desired ground resistance

values are shown in Figure 14. Impulse flashover values of this structure are higher than in the single-circuit structure because the flashover paths are longer. Because of structural strength, the economic span length of 2-circuit pole lines is shorter than for single-circuit pole lines. The shorter spans increase the effective impulse flashover values. Thus for the same lightning current protection level allowable ground resistance values become higher than for the single-circuit design.

Figure 15 shows a lightning resistant structure with 69-kv clamp top pin insulators on one side of the pole and a 12.5-kv circuit on the other side.

Outage Record

The performance record of the four types of wood-pole transmission lines discussed previously, classified in types of construction, is summarized in Table II.

Figure 16 shows outages classified by types of construction graphically. Wood-insulated lines without shielding and grounding had a less satisfactory record than lines with no attempt made to protect against lightning. The line with fair shielding, inadequate grounding, and low flashover values due to steel bayonets and steel braces had a record of few lightning outages. The lightning outages on lines of modern design approach zero.

It is interesting to note that as the designs for protection against lightning improved, outages due to other causes were reduced materially. This may be due to:

1. Modern lines have greater conductor spacing than most older lines. This should reduce number of phase-to-phase short circuits.

2. Modern lines are designed to minimize the possibility of dancing conductors getting together by maintaining a minimum relationship of conductor sag to conductor arm spacing.

3. Modern lines are relatively new and designed to provide a greater safety factor.

4. Modern lines are relatively new and still have better tree clearance.

System Operating Improvement

Construction of scientifically designed transmission lines of adequate lightning-resistant quality should result in a predictable decrease in lightning flashover. The correctness of this theory should be demonstrated by a decrease in lightning outages in our operating record.

An analysis of all lightning outages on 33- and 69-kv wood-pole lines was computed for each year from 1932 to 1947 inclusive. The per cent miles of lightning-resistant lines for each year for the same period was calculated also. The results of the calculations are shown in Table III.

Composite graphs were then plotted so that 100 per cent of the lines made lightning resistant would correspond to zero lightning outages; and 5.6 per cent, which was approximately the per cent shielded and grounded lines prior to 1938, would correspond to the average outages for the period prior to 1938. The composite graph is shown in Figure 17. Figure 17 shows that since 1932 the per cent miles of lightning-resistant lines has increased from about five per cent to over 40 per cent and lightning outages have decreased about one-third, in other words, flashovers from lightning are decreasing directly in proportion to the per cent of lines we have improved.

A trend curve often portrays results of a change better than a year-by-year curve. Storm frequency and severity varies from year to year. Our experience with lightning-resistant lines extends over a 10-year period, and over various parts of the state. A 6-year trend curve, Figure 18, was plotted from the same data given in Table III. This also shows a close and direct relationship between the per cent reduction in outages caused by lightning and the per cent of the system constructed on a lightning-resistant basis.

Figure 19 (above). Overhead ground wire burned by lightning

Figure 20 (right). Overhead ground wire burned by lightning

Ground Wire Burn Downs

For shielding wires we use a small high-strength composite strand with equivalent current capacity of number eight copper. In a few cases we have used number two aluminum cable steel reinforced or number four solid copper. Strength and current capacity have been thought ample for the service required. However, we have had two cases wherein lightning had damaged small shielding conductors.

In one case, a number eight 3-stranded copper-steel shielding wire was burned in two. The burned conductor ends are

shown in Figure 19. This was found just after a lightning storm. A witness stated that lightning struck at the location of the burned shielding wire. A very rigid inspection of the power conductors of both the transmission circuit and its underbuilt distribution circuit failed to disclose any evidence of power arcs. There was no record of any circuit breaker operation on either circuit which could possibly be involved in the burn down. There is no reason to believe that there was 60-cycle current contributing to this burn down of the shielding wire.

In another case, a number two aluminum cable steel reinforced shielding wire was found after a severe lightning storm with all aluminum strands burned through, the steel being undamaged. This conductor is shown in Figure 20. Construction of this transmission circuit had just been completed and the circuit was not energized until after the mentioned damage occurred. A witness stated that there was a lightning stroke at the location of the conductor burn down. There seems to be no possible way for 60-cycle current to have contributed to this damage. To date, the limited number of such occurrences in the year-miles of our experience are so few that we do not feel justified in installing any larger conductor to prevent such damage.

Conclusions

1. Full advantage of the impulse insulation strength can be obtained by inexpensive methods.

2. Due to the shape of the lightning severity curve, flashovers from lightning decrease more rapidly than the ratio of increased structure impulse insulation strength.

3. Ground resistance should be determined by the protection desired and the minimum impulse insulation of any of the conductors by any of its possible flashover paths.

4. It is desirable that the minimum flashover path be directly from conductor to down lead wire through air and not over wood in order that splintering of wood will be avoided.

5. Small, high-strength, shielding wires result in inexpensive construction. The few cases of trouble to date do not justify larger conductors and more expensive construction. This item should be reviewed from time to time to be certain that the present opinion is not based on insufficient data.

6. It is expected that ultimately our transmission system will be practically immune to lightning. Outage expectancy will be of the order of one outage per 100 miles per year, and few of these will cause damage.

7. No application of pure engineering theory has produced results more gratifying than to see the reduction of lightning outages of our entire system almost directly in proportion to our prediction.

Discussion

Opie D. Evans (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): The authors are to be commended for providing the industry with their experience in the design and operation of lightning-resistant wood pole transmission lines. Experience is still our best teacher, and all of us interested in this subject are indebted to the authors for their efforts in providing us with the information contained in this paper.

At the beginning of the paper, my attention was directed to the large number of outages attributed to causes other than lightning. For example, on the 45.1 miles of 69-kv line shown in Figure 4, outages listed as due to other causes are 21.1 per 100 miles per year as against only 6.5 outages per 100 miles per year due to lightning. Trip-outs due to causes other than lightning on the 66-kv system of the Oklahoma Gas and Electric Company are less than 25 per cent of those caused by lightning. It would be interesting to know if some of the outages, listed as due to causes other than lightning, were caused by sleet and glaze storms.

The authors state that, on two 69-kv lines on which there was wood insulation without shielding wires, the insulation of the line was so high as to cause failure of the substation transformers, even though lightning arresters were used to protect the transformers. They further state that this trouble was corrected by reducing the line insulation in the spans adjacent to the substation. If this lowering of the line insulation did correct this trouble, then it certainly resulted in more line trip-outs. This does not seem to be the proper approach to this problem. Modern lightning arresters should protect the transformers from all such disturbances if the breakdown values of the transformers and lightning arresters are co-ordinated properly and if the arresters are properly applied. The purpose of the arresters is to protect the substation from such disturbances rather than have the lowered insulation of the line protect the arresters and transformers.

It is interesting to note in Figure 7, that a different number of insulators is used for the various phases. This would increase the conductor spacing which, I gather, was the primary purpose of this type of construction. It is not believed that the variation of the coupling factor between the shield wires and the three phases would justify the use of such design as standard.

Good design necessitates that careful consideration be given to glaze and sleet storm protection as well as to lightning protection. This is particularly so in our territory where sleet and glaze storms are quite prevalent. The clearances shown in the authors' designs for the single pole lines would never be acceptable in our section of the country unless the spans were very short, in which case an uneconomical design would result.

The Oklahoma Gas and Electric Company has under construction, or in the design stage, approximately 150 miles of 138-kv wood pole line and 125 miles of 69-kv wood pole line. It has been our experience that, when both lightning and sleet storms are considered, the *H*-frame type of construction provides the best and most economical design, and most of the foregoing lines are of this type of construction. Two shield wires are used with a shielding angle of 30 degrees or less. Adequate midspan clearances are provided for lightning and "dancing" conductor protection.

In some cases, due to rights-of-way restrictions or for other reasons, it becomes necessary to use single pole design. In our single pole design we use construction similar to Figure 4 of the subject paper. A 10-foot wood arm with wood brace is used for the top conductor and a 12-foot wood arm with wood brace is used for the two lower conductors. A shielding angle of 30 degrees or less is maintained for lightning protection. A 5/8 inch round steel auxiliary crossarm brace rod is used in this design to overcome the unbalanced load on the top crossarm. This rod is bent to shape and threaded at both ends. One end of this rod is attached to the unloaded end of the top crossarm and the other end is inserted in the pole five feet below the top crossarm. Vertical clearances between conductors, and between conductors and shield wire, are at least as much as 125 per cent of the heavy loaded sag plus six inches. Spans around 350 feet are used when possible, and adequate midspan clearances are provided for lightning protection.

For our transmission lines, no particular design is used to obtain a low-ground resistance other than coiling the wire around the butt of the pole and using a galvanized

pole ground plate on the bottom of the pole. A 1-bolt guy clamp is inserted in the pole ground wire about 8 feet and 6 inches above the ground to provide an easy way of disconnecting the pole lead from the shield wire to measure the pole ground resistance. Should we experience undue trip-outs due to lightning, we intend to measure the pole ground resistances and install ground rods or counterpoises in those places where ground resistances are excessive. One 69-kv line (5.55 miles of *H*-frame construction and 11.38 miles of single pole construction) using this grounding scheme was constructed in 1937. Ground resistances were measured one year later and 30.9 per cent of the pole grounds measured 20 ohms or less and 64.5 per cent of the pole grounds were 50 ohms or less. Calculations show that we can expect less than six outages per 100 miles per year with our single pole design (using five 10-inch diameter, 5¾-inch spacing insulators) if the pole ground resistances are 50 ohms or less.

The possibility of offsetting the pole ground wire from the pole to obtain advantage of the pole insulation is very intriguing. It certainly is desirable that the minimum flashover path be directly from the conductor through air to the down lead, to prevent splintering of the wood. Such co-ordination may be difficult to obtain, however, with suspension insulators under all conditions. The resulting windstorms which accompany many of the rains in this section of the country could reverse the co-ordination on one or two of the phases. The use of stud bolts to offset the down lead is a novel idea and one well worthy of consideration. We have often considered offsetting the pole down lead but we were afraid that by attaching the pole ground lead to the shield wire, a fatigue point and possible future source of trouble would be established.

In Figures 9 and 10, the offset lead is shown as brought down on the crossarm side of the pole whereas in Figures 5 and 6 the offset down lead is shown on the back of the pole. From an operation and safety standpoint, the placing of the offset lead on the back side of the pole (Figures 5 and 6) seems preferable since it provides better clearances for replacing arms and braces on an energized line.

G. E. Dean (Public Service Electric and Gas Company, Newark, N. J.): On January 1, 1948, the Public Service Electric and Gas company had 693.8 circuit miles of overhead open wire 26-kv transmission lines. Of this amount approximately 15 circuit miles of lines were erected on steel towers leaving 679 circuit miles on wood poles. For 1947 the over-all performance of this 26-kv wood pole transmission system was 12.0 lightning outages per 100 miles per year compared to 38.2 before protection was installed. This total of 679 circuit miles of 26-kv wood pole construction was composed of 524 circuit miles of lightning protected circuit and 155 circuit miles of unprotected wood pole construction. In other words, 77.2 per cent of all our wood pole 26-kv transmission lines were of lightning-protected construction.

For a number of years complete operating data on the performance of lightning protection for wood pole 26-kv transmission was kept for comparison with unprotected lines. These data indicated that 85 per cent of all lightning interruptions were avoided by the use of the elevated protected phase wire scheme. Actual values of lightning trip-outs per hundred circuit miles per year for the five year period were 38.2 for the unprotected lines and 5.8 for the protected lines. Referring to the six year trend curve in Figure 16 for the condition where 38 per cent of all transmission has received lightning protection, the elevated protected phase wire scheme used by this company would give 25.9 lightning outages per hundred miles per year as compared to 27.5 for ground wire protection.

Because of this record of reduction of line outages caused by lightning, additional lines will be reconstructed to provide the protection, all new lines or portions of lines, however small, are built with the lightning protected type of construction and all individual pole replacements in unprotected lines are made with adequate pole height and with crossarm details appropriate for protection. These policies will be continued so that ultimately all lines will be protected.

The lightning protection scheme used on these 26-kv wood pole lines is based upon using 1-phase conductor as a combination ground wire and phase wire. In detail, for single circuit pole lines one phase is elevated above the other two by placing it upon a pole top or ridge pin. This elevated phase conductor is then provided with lightning flashover protector tubes to drain off lightning discharges and to cut off any power follow-up current at the first current zero. For double circuit pole lines three crossarms are used and the two top phase conductors are provided with flashover protector tubes. It is not necessary to equip the elevated phase conductors with tubes at each pole and the distance between protected poles varies with the resistance of the ground connection of the tubes. For single circuit construction, the distance between protected poles reaches 1,000 feet for 10-ohm ground resistances, and for double circuit poles the distance between protected poles reaches 950 feet for 10-ohm ground resistances.

With this background, it is difficult to justify the installation of overhead ground wires. In fact, there is more to be considered than the higher cost of the ground wire protection since this company experienced so much mechanical trouble with ground wires on wood pole transmission lines that their use was discontinued some years ago. Large Copperweld ground wires were used for these ground wires under discussion.

It is further felt that the use of small size ground wires may be difficult to justify because of the existence of data which show that ground wires under high mechanical loads may be burned down by lightning currents which would not fuse similar wires under no mechanical loading.

R. M. Schahfer and W. H. Knutz: Evans calls attention to the ratio of outages from causes other than lightning to those caused by lightning on the line shown in Figure 4, this ratio being 3.25 to 1; compared to a ratio of 0.25 to 1 for his 66-kv system.

In making the foregoing comparisons at least two general considerations should be observed.

1. The method of tabulating line outages and what is included.

2. When comparing to lightning, the lightning resistant characteristics of the lines under consideration.

Our method of recording line outages accounts for each time service on the line is interrupted. Therefore, we include as outages interruptions to service caused by the public, line and substation equipment failure, relay errors and inadequacy, operating errors, switching surges, overloads and emergency transfer of power.

The 16 year record of outages per 100 miles per year for the line shown in Figure 4 has been itemized as shown in Table I.

Of the total 27.6 outages per 100 miles per year 7.0 were caused by a very high wind displacing conductors so that contact was made with the steel arm braces. This wind lasted several hours and considerable damage resulted throughout northern Indiana and Illinois.

Line performance may be compared in several ways, one interesting method is to take the ratio of other than lightning outages of a particular line and compare lightning outages of this and other lines to this value. Using other than lightning outages experienced on the line shown in Figure 4 as a basis of comparison, we obtain the ratios given in Table II.

We agree that good design must give consideration to sleet and wind as well as to lightning protection. To these factors we add several clearance conditions and economics. However, our paper was confined to the performance of lines with regard to lightning. We note that Evans uses a minimum vertical conductor clearance of 125 per cent of heavy loading sag, plus six inches. We experience little trouble with lines using pin-type insulators which have span length, cross arm spacing and conductor sag so co-ordinated as to have vertical conductor separation equal to the sag of the upper conductor plus 20 per cent of the sag of the lower conductor, at 32 degrees Fahrenheit, with 1/2 inch radial ice. For suspension insulators 75 per cent is used. This method of determining vertical conductor separation provides for different types of conductors being used on the same structure.

Because of the wide separation of arms necessary to provide vertical conductor clearance when suspension insulators are used, and due to the difficulty, mentioned by Evans, in co-ordinating insulation when insulators are displaced by wind, we are giving serious consideration to the use of clamp top pin type insulators on 69-kv lines. When suspension insulators are used, we balance insulation against ground resistance on the assumption that conductors will be displaced toward the grounded down lead by 30 degrees.

The grounded down leads on our first lightning resistant lines were installed on the side of the pole away from the arms. The impulse strength of the pole structure is not changed if the down lead is on the arm or opposite side of the pole. These two locations were discussed at great length in our various safety groups, opinions being closely divided. Those in favor of locating the down lead on the arm side finally won. No fundamental principles of design being involved, we made the change and are installing the down lead on the arm side of the pole.

Table I. Outages Per 100 Miles Per Year on the Semi-modern 69-Kv, 45.1 Mile Line, from 1932 to 1947, Inclusive

Wind	7.0	Equipment failure	3.1
Lightning	6.5	Trees	1.5
Unusual operations	4.7	Unknown	1.0
Dancing conductors	3.1	Caused by public	0.4
Birds and animals	0.3		

No trouble has been encountered to date with fatigue at the point where the down lead is attached to the overhead ground wire, the attachments being made by using a very slack loop. This is shown in Figures 10 and 12. A detail standard is issued to our construction forces regarding this attachment.

Dean calls attention to mechanical troubles experienced with overhead ground wires. Our company, like many others, has had sad experiences in burned down overhead ground wires and we followed the general practice of removing them. These troubles occurred on old type construction. Overhead steel ground wires were often attached by means of U bolts to steel bayonets. Steel braces were used on crossarms, often the arms were short. Grounded down leads were attached directly to the pole and grounded about every fifth pole, with ground resistance usually high. Some of the overhead ground wires were steel and rust weakened them, some were copper covered steel and the copper peeled off. Consequently, grounding installations on these lines not only lacked mechanical stability but contributed toward low structural flashover values.

Practically every lightning discharge would result in a flashover. Due to low insulation values, flashover consisted of both lightning current and 60-cycle current. Engineers could not determine which caused the damage.

Our ten year experience justifies the use of small size, high strength, corrosion resistant overhead ground wire as to both economics and reliability. There is no comparison between the old type lines and the present lines which are balanced mechanically and electrically. Our modern lines, described in the paper, have given very satisfactory service. The only two burn downs of overhead ground wires experienced in ten years is described in the paper.

We do not believe these two cases of burn downs are sufficient to warrant the expense of adopting larger size overhead ground wires. Larger wires increase structure loading, require more poles and pole fixtures with resultant increase in investment and maintenance charges.

Table II

Type of Line	Outages per 100 Miles per Year: Other	Outages per 100 Miles per Year: Lightning	Ratio of Other Outages on Semi-modern Line, to Lightning Outages of Same and Other Type Lines
Semi-modern	21.1	6.5	21.1 to 6.5 = 3.25 to 1
All 1932–1938	31.7	40.1	21.1 to 40.1 = 0.53 to 1
Wood-porcelain insulated	29.6	48.9	21.1 to 48.9 = 0.43 to 1
Modern	5.1	1.0	21.1 to 1.0 = 21.1 to 1

We have a section of 33-kv line, installed in 1938, which is particularly exposed to lightning. The ground is higher than surrounding areas and structure resistance somewhat above other sections. Magnetic links have been installed in this area and measurements of some severe strokes have been obtained. No flashovers resulted.

About a year ago we lowered about a mile of the overhead ground wire on this line and several engineers and several construction men closely inspected the entire length. No evidence of damage was found.

A New 150-Kilowatt Transmitter for Standard Band Broadcasting

T. J. BOERNER
NONMEMBER AIEE

RADIO BROADCASTING service in most densely populated centers of the world is now handled economically by a plurality of medium power transmitters located at strategic points adjacent to the population centers. High-power radio broadcast service employing medium frequency, amplitude modulated transmitters provides an unexcelled, economical vehicle for education and entertainment of large population groups in sparsely settled areas. The modern 150-kw transmitter described herein was designed to meet the need for service in these areas. Fundamentals were established in 1945 and active product design started early in 1946. Design considerations and performance specifications are presented along with illustrations and performance data on the final product.

Basic Design

The prime design objective was an efficient, compact transmitter capable of delivering fine performance economically. New design features reflect full cognizance of prior art on medium frequency broadcast transmitters. Circuits, tubes and components were investigated.

A carrier frequency range of 540 to 1,600-kc was chosen as the band in greatest use internationally for medium frequency broadcasting. The high-level system wherein a class *C* final amplifier is amplitude modulated by a class *B* modulator was the final circuit choice, after a study of high efficiency systems to select the most advantageous circuits for 150-kw carrier output. The highest over-all efficiency of the high level system along with the relative ease of adjustment outweighs the disadvantages of such factors as additional tubes and large size modulator components. Lowest total power input results in power savings which would otherwise be a major operating cost factor at many of the locations where the transmitter would be installed.

An operational advantage of the high-level system is the ease with which the transmitter can be adjusted by operating personnel of limited skill to maintain high quality performance. This advantage is due to the fact that a moderately economical tube complement provides the required performance without the use of over-all feedback which normally calls for critical radio frequency circuit adjustment. The final radio frequency power amplifier in the high-level system is driven well beyond saturation thus swamping hum generated by a-c filament heating as well as providing ample grid swing for modulation peaks.

The disadvantage of higher initial tube cost in the high level system is not an important factor in over-all economy because operating conditions are conservative thus resulting in exceptionally long tube life. Size of modulation transformer and reactor are not an imposing problem because circuit advances and transformer design techniques learned in recent years have resulted in reduced size and lower cost of these components. Combined weight of transformer and reactor in recent 50-kw high-level transmitters is 9,700 pounds as compared to 20,000 pounds in a transmitter of the same rating designed in 1938.

The *9C21* water cooled tube was chosen for use in the final amplifier of the audio and the radio frequency systems. Prior experience with the *9C22* tube, the air-cooled counterpart of the *9C21*, for power amplifier and modulator service in 50-kw high-level transmitters has been entirely satisfactory. Average life at the first installation using this tube type has passed the 10,000 hour mark. Some higher power tube types are in existence but operating experience did not appear sufficient to warrant their consideration.

Figure 1. Block diagram, 150-kw broadcast transmitter

Paper 48-132, recommended by the AIEE communications committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21-25, 1948. Manuscript submitted March 1, 1948; made available for printing March 17, 1948.

T. J. BOERNER is with the Radio Corporation of America, Camden, N. J.

Engineers who contributed to the design were J. C. Walter and staff on the over-all system, N. J. Oman on audio-frequency circuits and T. N. Newman on mechanical features.

This paper also was presented at a meeting of the AIEE New York (N. Y.) Section, April 23, 1948.

Figure 2. Model of single floor layout showing access space

Figure 3. Floor plan, single floor layout

High-power rectifier tubes considered were the type *870-A* and the type *857-B*. The *870-A* was considered from the standpoint that one rectifier could be used for d-c voltage supply to both the power amplifier and the modulator. In this case d-c voltage is limited, by the modulated rating of the *9C21*, to 12.5 kv for radio frequency power amplifier service. A conservative operating figure is 11.5 kv. At this voltage six type *9C21* modulator tubes would be required to modulate four type *9C21* power amplifier tubes because of the grid current requirements in modulator service. A driver of many times the power capability of the actual final design choice would have been required for a modulator tube complement of four *9C21* tubes at 11.5 kv. The alternative of two rectifiers, one operating at 11.5 kv to supply four *9C21* power amplifier tubes and the other at 14 kv to supply four *9C21* modulator tubes, was chosen as the more economical system. Each rectifier operates with six *857-B* tubes in a 3-phase full wave circuit. The cost of 12 *857-B*'s is $2280.00 as compared with a cost of $7050.00 for six *870-A*'s plus two extra *9C21*'s required in the modulator. Savings represented ($4770.00) neglect the additional cost for six versus four modulator tube positions. Cost of spare tubes must also be considered. The two high-tension rectifier transformers are energized from a single control circuit breaker so that no additional expense is involved in the primary supply.

Savings were also realized on rectifier filter components. Ripple voltage on the power amplifier supply could be considerably higher than would be required for the modulator because of the filtering contributed by the modulation reactor. The separate criteria for modulator and power amplifier filtering resulted in lower total filter component kilovolt-amperes than would have been the case with a single rectifier. The saving appeared to be greater than the cost of the additional rectifier.

The advantages of air cooling versus water cooling were studied. The final decision was in favor of water cooling because of dissipation limitations on available air cooled tubes such as the *9C22*. Here again two additional tubes would have been required in the modulator for air cooled operation and the additional cost along with a cumbersome air duct system appear to outweigh the lower maintenance advantage of air cooling. A study of water cooling circuits using four *9C21*'s in the power amplifier and four in the modulator indicated that a simple system with moderate pressure and with water flow in series through each pair of tube jackets would suffice.

A 460-volt 3-phase power supply was selected as the most economical to meet the technical requirements. Particular attention was paid to the necessity for high-speed protection on rectifier arc backs and high power tube gas flashes. 460-volt switchgear provides the required protection speed at a cost substantially less than for switchgear operating on higher voltages. A further advantage of the low-voltage system results from the fact that a 380-volt power supply is standard in a number of countries where the transmitter might be installed. The transmitter design proceeded on the basis that operation at either 460 or 380 volts was possible by means of taps on the two main rectifier transformers and on two auxiliary transformers included as part of the transmitter.

Performance specifications were set up and are referred to later with actual performance data. Certain other features were included to improve reliability for broadcast operating groups. Provision is made for emergency operation at reduced power with half the number of power amplifier and modulator tubes. The two radio frequency amplifiers preceding the final stage were equipped with an extra tube socket. A spare tube can be in place with water and air applied so that it is ready for immediate connection of filament, grid and plate supply in case of failure of the active tube. A water-cooled dummy load is provided for convenience on initial setup, routine maintenance measurements, or subsequent line-up during transfer to another operating frequency. Water coolers and pumps are in duplicate although one pump and one cooler will be sufficient on normal operation at most times. Both coolers are required only when cooling air temperature exceeds 40 degrees centigrade. Final installation atmospheric conditions were considered. Design proceeded on the basis that full power operation could be realized at 8,000 feet above sea level. Figure 1 is a block diagram showing major components and tubes of the final design.

Detailed Description

Figure 2 is a model of the complete transmitter as it would appear if installed on a single floor. A fireproof wall between the transmitter and the oil-filled

Figure 4. Fundamental circuits, 150-kw broadcast transmitter

Figure 5. High power rectifier circuits

apparatus is omitted in this view. It will be noted that rear access space to individual units was well planned. Figure 3 is a floor plan corresponding to Figure 2 showing dimensions of the space required for installation and disposition of various units described in subsequent paragraphs. Design was co-ordinated so that installation with a two floor layout would require no more floor space, the auxiliary equipment being mounted on the lower floor directly beneath the transmitter.

Figure 4 shows fundamental circuits incorporated in the final design. The radio frequency chain starts with a highly stable, electron coupled crystal oscillator of a type approved for use in broadcast transmitters by the Federal Communications Commission. Duplicate oscillators are provided with means for switching instantaneously from one to the other without loss of program. A switch is available to select an external frequency source if so desired. A buffer amplifier consisting of one RCA *828* pentode tube with conventional tuned circuits follows the oscillator. Voltage dividing capacitors in the buffer tank circuit provide a source of radio-frequency voltage to an external frequency monitor.

The first intermediate amplifier consists of two *810* triodes in parallel with transformer neutralization and variable inductor plate tuning. The following stage using one *7C24* triode has similar circuits and provides an output of approximately 2 kw to the third intermediate amplifier by means of inductive coupling. The latter stage, preceding the final power amplifier, uses one *9C21* triode inductively neutralized and with plate tuning accomplished by two variable pressurized gas capacitors in a pi network. Output of approximately 15 kw is supplied to drive the final power amplifier. The use of inductive interstage output coupling in the two stages preceding the final amplifier was incorporated to prevent mutual coupling through heavy current ground paths which would occur if a simpler direct coupling method had been used.

The final power amplifier circuits are similar to the preceding stage. Output coupling control is provided through variation of the output capacitor of the plate circuit pi network. A wide range of power output control is obtained by varying this capacitor with little effect on plate efficiency. A harmonic filter is interposed between the power amplifier output and the transmission line input. It is equipped with inductive and capacitive elements arranged so that a T or pi network can be used depending on which is more effective in suppressing harmonics at any harmonic load impedance encountered on final installation. The transmitter is rated normally to deliver power to a load impedance of 230 plus j0, the characteristic impedance of a 6-wire open line such as frequently used to carry transmitter power to the base of the radiator. Special components can be used for mounting in the harmonic filter where load impedance is a 50- to 70-ohm coaxial transmission line. In the latter case the harmonic filter serves as an impedance transformer as well as a harmonic attenuator.

It will be noted that all vacuum tubes in the radio frequency chain have individual cathode current ammeters and that all tubes with a rating of 2 kw or higher are equipped with individual over current relays which act to remove plate voltage supply in the case of tube overloads. Single ended circuits are used throughout the radio frequency chain for minimum number of components and simplicity in adjustment. The single ended design also avoids the complication of push-pull to single ended coupling for the final output. Circuits which might be responsible for spurious oscillation or harmonic resonance were kept to an absolute minimum. Inductance in the path from power amplifier plates to cathodes through the blocking capacitor and tank capacitor was held to a very low value through proper physical placement of components and the use of low-inductance interconnections. Motor drive on the tuning capacitors made possible the most advantageous placement of these units. Spurious oscillations between parallel power amplifier tubes was avoided by grouping the plates

on a common assembly and using the familiar resistor-inductor suppressor on individual grid connections.

Filament heating supply to the power amplifier tubes is double quarter phased so that each filament is excited 45 degrees advanced in phase from its adjacent tube. Single phase filament excitation will result in hum components of twice the power frequency due to the magnetron effect. Quarter phasing will eliminate the double frequency component and leave only those components of four times the power frequency or higher. The corresponding hum reduction is approximately 13 decibels. Double quarter phasing leaves only components of eight times the power frequency or higher and effects a further reduction of approximately six decibels. A total of 19 decibels is not actually realized because of other factors but experience has indicated that this system will provide at least 15 decibels reduction of the hum produced by the magnetron effect.

Modulator circuit design was an extension of principles learned in the application of an economical system used since 1941 on 50-kw transmitters. Amplifiers are push-pull throughout the chain. Low power circuits consist of a 2-stage voltage amplifier and include networks which maintain phase relations suitable for the application of feedback. The voltage amplifier is followed by a zero voltage gain, cathode follower amplifier which drives the modulator grids directly from voltage developed across the cathode networks. It will be seen that peak plate current of the cathode follower stage will be approximately the same as peak grid current in the modulator tubes. The proper choice of modulation transformer ratio and modulator d-c plate voltage provides adequate output for modulating the power amplifier even though the cathode follower driver has relatively low power output. Modulator efficiency is approximately 55 per cent at 100 per cent modulation. Feedback is applied from the modulator plates to the grids of the input voltage amplifier through a resistor-capacitor network having zero phase shift at frequencies many times the highest modulating frequency. A stabilizing rectifier is provided between modulator grids and cathodes. This rectifier acts to prevent spurious oscillations which might otherwise develop when modulator grid current swings negative during a portion of the audio frequency cycle. Spurious oscillations of small magnitude may still appear due to shock excitation by steep program wave fronts. These oscillations do not affect modulator efficiency and the voltage at the spurious frequencies is attenuated to a negligible value by the "L" section network between the modulation transformer secondary and the power amplifier. The network also acts to maintain constant modulator output impedance up to 10,000 cycles per second above which the impedance rises rapidly.

Modulator tubes have individual cathode current ammeters and over current relays for indication and protection similar to those provided in the power amplifier. Each pair of modulator tubes has filaments excited in quarter phase relation to provide a hum reduction of a theoretical 13 decibels. Actual hum reduction in this case is approximately 10 decibels. The hum is further reduced by the feed-back circuit. A single-phase full-wave rectifier in the modulator provides fixed bias for the cathode follower and modulator tubes. Differential control on a bias bleeder network provides means for balancing the modulator static plate currents at a value of 150 milli-amperes per tube. A 3-phase full-wave rectifier with a half voltage tap supplies plate voltage to all low power tubes in both the radio frequency and audio frequency amplifiers.

Control relays and contactors for all

Figure 6. Power distribution circuits

Figure 9 (right). 15-kw intermediate amplifier showing spare tube in place

circuits are centralized in so far as possible in a single unit at the right end of the transmitter. This unit includes all over current relays and sequence relays required for proper starting and protection of circuits and tubes. A reclosing relay provides for three successive re-applications of power at spaced intervals when overload faults occur. If the overload persists after the third re-application of power, the relay will automatically lock out the closing circuit to prevent further re-applications of power unless manually reset by the transmitter operator. Control switches may be set up for complete automatic starting but switches are so arranged that the starting sequence can be interrupted manually at any of several points. Controls are distributed along the front panel of the transmitter at pertinent locations and are also duplicated on the centralized control unit. Circuits are arranged so that, if a control switch is open at any one location, power cannot be re-applied except by closing the control switch at that location. The usual safety features such as access door interlocks and high voltage grounding contactors are tied in with the control system to provide personnel protection. Water

Table I. Performance

	Specification	Actual
Frequency Range	Any specific frequency in the band from 540 to 1,600 kc	535 to 1,605 kc
Power Output	150 kw unmodulated carrier power at transmitter output terminals	155 kw within other specification limits
Frequency Stability	Plus or minus 10 cycles per second	Not measured. Identical frequency source previously measured well within specification limits
Carrier Shift	Less than five per cent at any modulation percentage up to 95 per cent	1.5 per cent positive at 100 per cent modulation
Noise Level	Less than 56 decibels rmn below 1,000 cycles per second. 100 per cent modulation	57 decibels
Radio Frequency Harmonics	70 decibels below fundamental measured at one mile	Not measured. Circuits are included to meet specification requirements
Program Input Level	10 milliwatts plus or minus two decibels for 100 per cent modulation at 1,000 cycles per second	10 milliwatts minus one decibel

Figure 10. 150-kw power amplifier showing assembly of four tubes on a single base plate

Figure 12. 11.5 kv and 14 kv rectifiers with associated filter reactors

flow interlocks are provided in the return line of each separate water circuit. These interlocks are of the indicating type so that a reduction in flow can be noted before flow drops low enough to open the interlock contact. Indicating water temperature interlocks are also provided on the discharge side of each separate water circuit.

A supervisory console duplicates essential transmitter controls and indicator lights. The console also has the necessary switching and metering for control of program level and transfer to local microphone or transcription turn-table when required. A monitor rectifier to be located at the radiator tuning house provides an audio monitoring signal and also serves to shut off carrier through an auxiliary control relay when lightning causes antenna flash overs. The rectifier also provides a remote antenna current indication on the front panel of the transmitter.

Figure 5 shows circuits of the rectifiers which supply the power amplifier and the modulator. A spare tube with filament energized can be switched in quickly in case of failure of an active tube. Figure 6 is a single-line diagram of high power switch gear and distribution circuits included in the transmitter. Auxiliary distribution circuit breakers are located in the control unit at the right of the transmitter. The incoming circuit breaker, the main rectifier circuit breaker and the delta-wye switch are located in a separate cubicle which may be placed near the main rectifier transformer to simplify heavy current interconnections. The delta-wye switch provides a convenient means for obtaining 0.57 times the normal anode voltage for initial adjustments and tests. Probable telephone line interference due to harmonics generated in the main rectifiers is reduced by connecting the high voltage side of the 11.5-kv rectifier transformer delta while the high voltage side of the 14-kv rectifier transformer is wye connected.

The incoming circuit breaker has time delay over current protection through an auxiliary induction type relay which can be adjusted so that the circuit breaker

Figure 11 (left). Push-pul class B modulator

Figure 16. Performance

Dotted lines are specification limits

will not open on a fault unless all succeeding circuit breakers have failed to open. Time delay adjustment of this circuit breaker is effective up to ten times normal current rating above which the circuit breaker will open instantaneously. The circuit breaker feeding the high-power rectifier transformers is tripped by an auxiliary induction type over current relay which has adjustable settings for both inverse time and instantaneous operation. All other circuit breakers in the distribution system are provided with dash pot or thermo-element inverse time protection as well as instantaneous tripping at eight to ten times normal rating.

A one-to-one ratio, 200-kva transformer provides the impedance necessary to use circuit breakers of moderate interrupting rating in the secondary distribution circuit. This transformer is also equipped with taps so that the transmitter can be operated from a 380-volt power supply without changing taps or ratings on any transmitter elements in the secondary distribution system. Two single phase automatic voltage regulators connected open delta regulate the filament supply to high-power tubes to within 1.5 per cent. A 75-kva special transformer provides the 45 degree phase shift required by the double quarter phasing, filament excitation scheme described previously. Four *T* connected transformer pairs provide the second step for quarter phasing.

Water cooling is provided by a closed system including a distilled water storage tank, two pumps in parallel and two coolers in parallel. Valves are provided so that pumps and coolers may be cut in or out without interrupting transmitter operation. Coolers are the unit air conditioning type for water to air heat exchange. Additional valves in the power amplifier, last intermediate amplifier and modulator allow isolation of any two *9C21* tubes without shutting down the complete water system to change a tube.

Figures 7 to 16 inclusive show the final product as set up for test at the manufacturing plant. The general arrangement of various units on the test floor was carried out as near as possible in accordance with recommended final installation plans so that any peculiarities introduced by discrete connector lengths could be noted and corrected prior to final installation.

Performance

Figures 16, 17, and Table I show typical test floor performance data at 640 kc compared directly to performance specifications. It will be noted that an ample margin exists in all cases to cover variations which might be encountered in field installations. Final test, of course, showed up some faults which were overlooked during the design stage. These faults did not require any major changes but are noted here for their interest.

Figure 15. Modulation transformer and reactor (left); 11.5 kv and 14 kv rectifier transformers (right)

Figure 17. Power input

Dotted lines are specification limits

The modulator showed unstable operation at frequencies above 5,000 cycles per second when tests were started. Careful measurements and investigation showed that instability was a push-push oscillation which could be eliminated by obtaining closer coupling between the two halves of the push-pull circuit. Closer coupling was obtained by redesign for lower leakage reactance in the unity ratio transformer which supplies equal audio voltages on cathode, suppressor and screen of the modulator driver tubes. The first and second intermediate amplifiers of the radio frequency chain were inductively neutralized in the original design. Some difficulty was experienced particularly in the second intermediate amplifier because of critical adjustments. The transformer type neutralizing of the final design eliminated this trouble and provided broadband, noncritical neutralization.

Installation

Installation details were worked out carefully so that the ultimate user would find installation easy. Terminal locations are arranged so that interconnections between units can be made with standard overhead wire ducts. High voltage bus work required at the installation site is limited to a minimum of straight runs and bends in either the two floor or single floor layout. It is possible to install this transmitter within an existing building with a minimum amount of building modification. An installation material kit provides all bus work items, wire, insulators, water piping, valves, hardware and special tools required for installation with either the single floor or two floor layout.

Conclusions

A highly efficient, compact 150-kw transmitter has been developed for medium frequency broadcast service. Excellent performance can be obtained and maintained economically without employing highly skilled operating personnel. Component and tube ratings are such that the transmitter will provide adequate trouble free service for a long period at minimum cost.

The design principles embodied in the 150-kw transmitter can be extended to higher powers if and when required.

No Discussion

The "Superimposed Frequency Test" for Induction Motors, or S. F. Test

M. P. ROMEIRA
NONMEMBER AIEE

THE FEEDING of 3-phase currents to the slip rings of induction motors, either at slip frequency for speed regulation, or at any other frequency such as in differential motors for selsyn applications, is well known. The applications now in use suggest a method for testing induction motors under equivalent full-load conditions without the use of any kind of loading machine and with a minimum of power consumption.

This paper presents a method for taking a full-load slip ring motor efficiency and heat-run test under conditions of no-load power supply; a discussion of the theory of operation and the accuracy of the results; and a similar method for testing a squirrel-cage motor using a slip-ring motor as the load machine.

The procedure is simply to run the motor at no load with the slip rings short circuited through a voltage regulator or another alternator capable of providing full-frequency power supply. Sufficient voltage is applied to the rotor slip rings to circulate full-load current through the stator.

Connections and Operation

Figure 1 shows in single line diagram, the necessary arrangements and connections for this test. The operation is as follows.

A 3-phase voltage regulator (*VR*) is provided, capable of varying the supply voltage from zero to about one quarter of the open-circuit slip ring voltage. The regulator should preferably operate in conjunction with a transformer with windings arranged for various voltage and current combinations in order to extend the range of the set.

The primary (*S*) of the motor is connected straight to the supply; the slip rings (*R*) are connected to the output side of the voltage regulator (*VR*), preferably through a variable resistor (*WR*); and the input side of the voltage regulator is connected to the same supply of normal frequency voltage as the motor primary. Then

1. With the rotor circuit open at *WR*, close the supply to the stator, and measure the slip-ring volts.

2. Close the supply to *VR*, and adjust the voltage to one quarter or less of the open-circuit slip-ring voltage.

3. On gradually cutting out the resistance *WR* the motor will run up to speed, and if the direction of rotation of the stator field and injected rotor field are the same, the current on the stator will increase.

4. Adjust *VR* to give on the stator whatever current loading is finally required, and take readings of volts, amperes, and watts supplied to both the stator and rotor.

The voltage regulator *VR* may be replaced by an a-c generator, in which case the resistor *WR* may be dispensed with altogether. This, however, does not appear to be advisable.

It will be found generally that both stator and rotor currents are perfectly balanced unless there is some fault in the motor, and the wattmeters W_1 and W_2 connected in the primary and secondary circuits will read respectively the no-load losses, and the copper losses at the stator current loading used. The sum of the two gives the total losses, subject to certain corrections. The power factor in the primary circuit is constant and equal to that obtained under normal no-load conditions; the secondary power factor is substantially the same as that obtained under locked-rotor conditions.

Theory of the Superimposed Frequency Test

1. Consider the motor connected to the required test equipment as shown in Figure 1, and running light under full voltage and frequency with its slip rings short circuited, and the voltage regulator set unexcited; the wattmeter W_1 gives the total no-load losses. If the short circuit across the rings is removed, thus introducing the resistance of the *VR* secondary in the rotor circuit, the speed will drop very slightly and the reading of W_1 will increase slightly. Usually, the test transformer is considerably larger than the motor under test, so this increase will be negligible.

2. By exciting *VR*, a small voltage of normal frequency is injected into the rotor, which produces a field revolving in the same direction as the stator field (with the rotor). This field will cut the stator conductors at twice the normal speed (minus slip) generating in them a double frequency voltage *e* (Figure 2).

3. This voltage *e* combines with the stator applied voltage *E*, to give a resultant *ER* of normal frequency and somewhat distorted shape, leading the applied voltage *E* in one-half cycle, and lagging behind it in the next one-half cycle. This has a slight adverse effect in the losses which appear to be slightly increased by the rather peaked resultant voltage wave.

4. Relative to the rotor conductors, the speed of the revolving field created by the injected voltage *e* is the same as if the rotor

Figure 1. The primaries of both the motor (*S*) and the voltage regulating set (*VR*) are connected to the supply transformer (T_r)

The secondary or (*VR*) is connected to the slip-ring (*R*) of the motor preferably through a resistor (*WR*). Two sets of instruments W_1 and W_2 are connected respectively to the primary and secondary circuits

Paper 48-133, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 19, 1948; made available for printing April 7, 1948.

M. P. Romeira is designing engineer, General Electric Sociedade Anonima, Rio de Janeiro, Brazil.

Figure 2. The normal frequency voltage *E* supplied to the stator, combines with the double frequency voltage *e* induced thereon by the rotor double speed flux, giving a resultant voltage *Er*, whose peaked wave form may affect somewhat the iron loss

were stationary. Hence the rotor impedance to this voltage is the same as would be found in the "locked rotor test." For a given injected rotor voltage, and, therefore rotor field strength, the voltage generated in the stator conductors is twice that for stationary conditions and so is the impedance due to the double frequency. Therefore the current induced in the stator will have the same value as for locked rotor conditions.

The only difference is that the stator is not short circuited upon itself, as it would be for the normal short-circuit test taken from the rotor side, but is, relative to these double frequency currents, short circuited through the secondary of the supply transformer.

Figure 3. A suggested arrangement whereby a squirrel cage motor (*SC*) may be tested, using a slip ring motor (*SR*) as a loading machine, the two machines running independently

5. An extra copper loss will thus be introduced which can be calculated once and for all for a given supply circuit.

Thus, the iron and other no-load losses are supplied at normal frequency and are therefore practically unaffected except for the slightly higher saturation due to the somewhat peaked wave forms. The copper loss is unaffected by the frequency, except in respect to eddy currents, for which correction curves will have to be worked out.

An idea of the usefulness of the test may be had from the following readings taken on a 40-horsepower 380-volt 50-cycle 725-rpm motor, supplied by a 150-kva transformer.

Stator volts = 380 amperes = 52.3
Rotor volts = 150 amperes = 93.0

The following readings were taken:

(A). No load test: $V_1 = 380$; $A_1 = 12.5$; $W_1 = 1.125$ kw; $\cos\phi_0 = 0.136$
(B). Locked rotor: $V_1 = 78$; $A_1 = 50.0$; $W_1 = 3.2$ kw; $\cos\phi_k = 0.476$
(C). *SF* test: $V_2 = 30$; $A_2 = 123$; $W_2 = 3.02$ kw; $\cos\phi_s = 0.472$

Subscripts 1 and 2 refer to readings taken on the primary or secondary respectively and *SF* is the superimposed frequency test.

The locked-rotor test was taken for comparison purposes only and the superimposed frequency test was taken with 51 amperes on the stator.

The short circuit current under full voltage is from test *B*

$I_s = 50 \times 380/78 = 243.5$

from *C*

$$D_s = \left(123 \times \frac{150}{30}\right) \times \frac{150}{380} = 243$$

(referred to stator)

Only a slight change occurs in the stator readings (W_1) when the rotor excitation is taken off; that is the no-load losses and power factor remain constant, therefore whatever energy is supplied to the rotor in the *SF* test must be entirely copper losses (I^2R and eddy loss) and equal the total copper loss of the motor.

Squirrel Cage Motors

It is believed that a modification of this arrangement, as shown in Figure 3, may enable us to provide a simple loading device for squirrel-cage motors.

The author realizes that the complete investigation of the various phenomena involved has been left untouched and hopes that tests now being carried on in Schenectady will clear up the many doubtful points.

Discussion

W. M. Schweder (General Electric Company, Schenectady, N. Y.): The superimposed frequency test proposed by Romeira may well prove to be of practical usefulness but a good deal of study will be required to work out a reliable procedure. It provides a means for measuring the stray losses of an induction machine in a single test, using only electrical measurements, and a means of simulating full load current and heating conditions without actually loading the machine. Also, it may be useful for design investigations.

To throw light on the accuracy of this method, tests have been made recently on a standard 20-horsepower 4-pole 60-cycle 440-volt 3-phase slip-ring induction motor. The motor was direct coupled to an electrically independent driving motor, and was tested under four separate conditions.

In the first test, the rotor was short circuited, and normal 3-phase excitation was supplied to the stator, while the driving motor was idling.

In the second test, the motor was driven at rated speed by the driving motor, the stator was short circuited, and 60-cycle reversed field excitation was applied to the rotor slip-rings, sufficient to produce full load rotor current.

In the third test, the conditions were the same as for test 2, except that the stator circuit was closed through the power supply system with no excitation on the primary side.

In the fourth test, the driving motor was again idle, the motor was driven from the primary side with rated voltage and frequency applied, and rated frequency reversed rotation voltage was applied to the rotor to produce full load current.

The test data are given in Table I for the four tests, the volts in each case being line to line, and the amperes the line values, under balanced polyphase conditions.

To analyze these data, it is convenient to consider the system as formed of two entirely independent circuits superimposed on

Table I

Test Number	Stator Volts	Stator Amperes	Stator Watts	Rotor Volts	Rotor Amperes	Rotor Watts	Mechanical Power Delivered by Driving Motor Watts
1	440	12.5	3,614	0	0	0	0
2	0	0	0	28	59	955	538
3		23.8	364	32.5	59	1,117	620
4	440	26	3,636	26	59.25	1,038	0

each other. The primary 60-cycle source of power delivers power to the stator, and produces a secondary slip frequency current, which creates some losses in the secondary power supply system. The secondary 60-cycle source of power similarly supplies power to the rotor, and produces a double frequency stator current, which circulates in the primary power supply system. The wattmeter in the stator circuit, therefore, reads the power supplied by the primary source, less the loss created in the primary system by the induced double frequency current.

Similarly, the wattmeter in the secondary reads the power supplied to the motor from the secondary source, less the losses created in the secondary system by the induced slip frequency current.

Let

I_1 = 60 cycle primary current

I'_1 = corresponding slip frequency secondary current

I_2 = 60 cycle secondary current

I'_2 = corresponding induced double frequency primary current

r_1 = primary resistance = 0.265 ohm per phase

r_2 = secondary resistance = 0.051 ohm per phase

r_3 = effective resistance of primary external circuit

r_4 = effective resistance of secondary external circuit

In tests 1 and 4, the power input to the primary supplies all of the rotational losses. In tests 2 and 3, the rotational losses are supplied by the driving motor, and they do not appear at all in the electrical measurements.

On this basis, the measured watts input to the stator, W_1, is made up of eight components:

A. The running light watts, made up of friction and windage, core loss, and magnetizing current copper loss. By test 1, this total is 3,614 watts.

B. The secondary copper loss due to the small slip frequency rotor current, $3I_1'^2r_2$.

C. The additional slip frequency loss produced in the external secondary circuit, $3I_1'^2r_4$.

D. One half the copper losses due to the double frequency primary current,

$\frac{3}{2} I_2'^2r_1$.

This is the part of this loss that is supplied by rotation.

E. The stray load loss caused by pulsation of the air gap leakage fluxes (due to rotation).

F. One half the double frequency stator core loss and leakage flux losses due to the double frequency current (the part of this loss supplied by rotation).

$G = \frac{H}{2}$. One half the double frequency losses produced in the primary power supply system by the double frequency current (the part of this loss supplied by rotation).

H. From the total of the foregoing, there must be subtracted the double frequency loss delivered to the primary system, $-3I_2'^2r_1$.

The measured watts input to the rotor is made up of six components:

K. The rotor copper loss due to the 60-cycle current, $3I_2r_2$.

L. The 60-cycle rotor core loss and losses due to leakage flux crossing the conductors (assumed negligible in this case, since the rotor has a wire winding). This loss may be large in a motor with a bar winding in the rotor.

$M = D$. One half the stator copper loss due to the induced double frequency current, $\frac{3}{2}I_2'^2r_1$ (the part of this loss supplied by transformer action).

$N = F$. One half the double frequency stator core loss and leakage flux losses due to the double frequency current (the part of this loss supplied by transformer action).

$P = G$. One half the double frequency losses produced in the primary power supply system by the double frequency current (the part of this loss supplied by transformer action).

$Q = C$. From the total of the above, there must be subtracted the slip frequency losses delivered to the secondary power supply system, $-3I_1'^2r_4$.

In test 2, W_1, F, and Q are zero, $K = 533$, $L = O$, $M = 229$. Therefore, $W_2 = 955 = K + L + M + N = 762 + N$, where $N = 955 - 762 = 193$ watts.

The mechanical input supplied by the driving motor in this test, in excess of friction and windage, was found by test to be 538 watts, and is equal to $D + F + E$.

Therefore, $538 = 229 + 193 + E$, and stray load loss $= E = 538 - 422 = 116$ watts.

In test 3, $W = -364$, $A = O$ (since the driving motor supplies the 1 friction and windage), $B = O$, $C = O$, $D = M = 229$, $E = 116$ (by test 2), $F = N = 193$ (by test 2), $K = 533$, $L = O$, $Q = O$. D and E are supplied by the driving motor.

Therefore, $W_1 = -364 = -H$, and $H = 364$ watts, whence $G = 182$ watts.
Also,

$$W_3 = 1{,}117 = K + L + M + N + P + Q$$
$$= 533 + O + 229 + N + 182 + O,$$

whence $N = 1{,}117 - 944 = 173$ watts, instead of 193 as found by test 2.
And,

$$620 = D + E + F + G$$
$$= 229 + E + 173 + 182$$

whence $E = 36$ watts, instead of 116, as found by test 2.

In test 4, $W_3 = 1{,}038 = K + L + M + N + P - Q$
$= 533 + O + 229 + N + 182 - Q$.

Taking $N = 183$, the average of tests 1 and 2, $C = Q = 1{,}127 - 1{,}038 = 89$ watts.
Also

$$W_1 = 3{,}636 = A + B + C + D + E + F + G - H$$
$$= 3{,}614 + B + 89 + 229 + E + F + 182 - 364$$

B is assumed to be negligible,
whence $E + F = 3{,}636 - 3{,}750 = -114$ watts,
instead of $116 + 193 = 309$ watts by test 2, or
$36 + 173 = 209$ watts by test 3.

This lack of agreement is quite unsatisfactory, and has not been explained as yet.

It should be pointed out, however, that there is a large 60-cycle pulsating torque under test 4 conditions, due to the coexistence of the full load double frequency current and the full voltage normal frequency flux in the stator (or the 60-cycle rotor current and the slip frequency rotor flux). This pulsating torque creates oscillations in the rotor speed and phase position, that are larger the smaller the inertia of the rotor. A check test made with a smaller flywheel effect in the rotor showed about 10 per cent higher losses. This would be expected, since the oscillations in the slip cause corresponding oscillations in the rotor resistance as viewed by the stator, giving rise to pulsations in the load current drawn from the primary power supply. These current pulsations create extra copper losses in both stator and rotor. The effect is the same as occurs in loom motors, whose load pulsates due to the shock of the flying shuttle.

The test can be made with less than normal frequency applied to the rotor, in which case the extra losses not occurring in a normal motor (F, G, L, and so forth) will be reduced. However, the amplitude of the speed oscillations will be increased.

A check was made on the pulsating torque in test 4, by mounting the motor on rubber blocks and measuring the angle of oscillation of the stator. The observed value checked fairly well with that calculated.

On the whole, this superimposed frequency test presents some interesting possibilities that deserve further study.

M. P. Romeira: In reply to Schweder's interesting discussion, and analyzing the exhaustive tests made, I note that in tests 1 and 4 the auxiliary motor he used coupled to the motor under test was allowed to run idle, and not uncoupled; this resulted in readings of primary input to the motor, of W_1 = 3,614 watts (test 1) and W_1 = 3,636 in test 4 (the SF test) neither of which represents even approximately the no load losses, which for this class of motor would be about W_1 = 1,000 watts; the watts representing the running losses of the idling rotor should be shown in the last column of Table I with a minus sign.

These two tests show, however, that the primary input remains practically constant for any phantom load thrown on the stator; and therefore adding W_2 = 1,038 watts supplied to the rotor in test 4 we have the total losses under SF conditions.

Hence the true efficiency = $20 \times 0.746/(20 \times 0.746) + 2{,}038 = 14{,}920/16{,}958 = 0.88$ is immediately obtained, subject to correction for the loss incurred in the resistance of the primary and secondary external circuits (r_3 and r_4) which was not given; this loss can always be readily obtained from sets of curves worked out for any given test floor setup.

Referring to tests 2 and 3, I take it they were both carried out with the rotor field revolving in the same direction as the rotor (as in test 4); unfortunately it would seem that typing mistakes or the like have crept into Table I putting zeros in the stator amperes and watts columns for test 2, instead of the value actually found $I^{2'}$ = 24 (as worked back from Schweder's figure in test 2 for $M = \frac{3}{2}(I_2')^2 . r_1 = 229$) causing considerable headache in trying to find out how zero amperes could be obtained in the shorted stator, with 59 amperes on the rotor; as this could be possible only with the rotor field going in the opposite direction to the rotation of the rotor, and the latter at synchronous and not rated speed, a doubt naturally occurred as to whether tests 2 and 3 were actually made in the same conditions; altogether I believe there are too many zeros in Table I, simply meaning that the respective readings were not taken, as in test 1 under the heading Rotor.

Tests 2 and 3 are specially designed to investigate if and to what extent the principle of operation of the proposed method of testing may affect the various losses and particularly the stray load loss, whose determination as separate from the "known" losses (core loss, friction and windage and primary and secondary I^2R loss) is of interest to the designer only.

In the SF test which is intended for the test floor, we get the total losses given us directly by the addition of two readings ($W_1 + W_2$), the stray loss being therefore included. In the usual tests, we get the first two items from the light run watts, and then with the motor stopped we measure separately the resistances r_1 and r_2 of the stator and rotor windings and calculate the

respective I^2R loss; the stray load loss is therefore not included, and must be determined by other tests, if we want to get the true efficiency. This is another advantage of the SF test.

Roughly I believe that, though the stray loss is partly iron and partly copper loss, since it is all due to rotation, it is supplied entirely by the primary supply in the SF test; and therefore the small difference in W_1 between tests 1 and 4 ($=22$ watts) represents the stray load loss multiplied by

$$\frac{\text{slip in test 4}}{\text{designed } FL \text{ slip}}$$

Thus, if the designed full load slip $= 5$ per cent, and we find 1 per cent slip under test 4, then the stray load loss $= 22 \times \frac{5}{1} = 110$ watts, if the tooth saturation is not too high; this appears to check fairly well with the value found by Schweder from test 2 which I believe is correct, since W_1 not being $= 0$ does not affect the result. But, in my opinion, it does affect indirectly test 3 because on passing from test 2 to 3, the stator watts decrease by $458 - 364 = 94$; and since the stator current remains practically the same $I'_2 = 23.8$ (instead of 24) for the same rotor current, the flux leakage will remain the same; but the stator power factor and watts have decreased. Therefore, to keep the speed constant, the input to the shaft has to decrease an equal amount; and 94 watts less than in test 2 must be subtracted from the total watts supplied to the shaft in test 3 to get the corresponding figure in the last column, or else added to that figure.

It seems therefore that instead of 620 in the last column for test 3, we should have $620 + 94 = 714$ watts.

Then $714 = D + E + F + G$ and $E = 714 - 584 = 130$ watts instead of 36, and $E + F = 130 + 173 = 303$ watts, which agrees quite closely with $E = 116$ and $E + F = 116 + 193 = 309$ from test 2.

Regarding test 4, it is not stated whether the supply to the rotor was drawn from the same source as the supply to the stator through a voltage regulator (as indicated in my paper) or from an independent generator; either way is permissible when the heat run only is desired; but when accurate segregation of the losses is required, I am afraid that any differences in wave form and absence of synchronism between the two independent supplies may introduce all sorts of unnecessary troubles, which may account for the discrepancies found.

Another advantage of this test is that, as is well known the impedance voltage taken in the usual locked rotor test, varies considerably with the position of the rotor, and an average value must be taken from a number of separate readings; while in the SF test with the rotor going at full speed the impedance values are automatically averaged out. Regarding the 60-cycle torque pulsations referred to under test 4 (SF test) conditions; it is not stated whether these pulsations are in the same or opposite direction for each successive pulsation or, if always in the same direction, (as might be inferred from the text since they appear to affect the speed) whether with or against rotation.

I was convinced from many tests made on different makes of motors, that these pulsations (barely noticeable as a characteristic rumble) do not affect the speed; I never noticed it on a tachometer and was under the impression that they cancel out not affecting either speed or phase position, though I admit not to have paid particular attention to that point. In fact, I found these pulsations a useful by-product when in a certain case they were the means of detecting audibly, a very bad case of a stator core loosely held by pressure screws to the outer ring frame; in this case, the horrible vibration was immediately checked by tightening up, which, without the SF test might have passed unnoticed. This would appear to indicate that the successive torque pulsations are in opposite directions; since were they in the same direction they would not cause such vibration, the stator pushing always in the same sense, instead of a push-pull action; and again, these pulsations might become less important if as explained before and I always did in my tests, the stator and rotor are supplied from the same and not independent sources.

All I can say in this connection is that if there are any pulsations in the load current drawn from the primary, they were never in my experience of a magnitude to be even noticeable.

In conclusion, it should be borne in mind that the test was proposed primarily as an economic method of giving a motor the required heat run at much smaller expense in power consumption as well as time and labor; the idea of using it simultaneously for the segregation of losses was only a more or less obvious corollary; and these can always be obtained by other methods if preferred, since it is not the determination of the losses that costs money; it is the heat run and preparations for the same.

Utilization of Electric Power in Open-Pit Copper Mining

S. F. FRENCH
MEMBER AIEE

H. SPEIGHT
MEMBER AIEE

Synopsis: At the outset it should be said that the utilization of electric power in the mining of copper ore as in many other branches of engineering requires only the application of sound electrical engineering knowledge, with particular attention applied to some of the special problems involved. It is well known to members of the Institute, and of the electrical engineering profession in general, that each industrial operation involves special features differing somewhat with the various processes, and so it is with the subject of copper mining. It becomes necessary, in order to illustrate specific principles, to restrict ourselves to the mining of one type of ore. It is our belief that many of these special problems arise in processing sulphide ore and the following outlines this interesting process together with descriptions of equipment and discussion of some of the problems involved.

Mining

THE TERM "open pit" is applied mostly to comparatively low-grade ore deposits which can be worked by open cuts or benches and where no underground mining is entailed. These pits are sometimes located on the side of mountains and other times are located in fairly level country, so that the pit proper may actually be a series of benches along a mountain side, or an open excavation ranging from several hundred to a thousand feet deep. In either case, the removal of the copper-bearing ore involves the moving of large tonnages of ore and waste daily.

Paper 48-134, recommended by the AIEE mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted March 9, 1948; made available for printing March 19, 1948.

S. F. French is electrical engineer, Anaconda Mining Company, New York, N. Y., and H. Speight is district engineer, Westinghouse Electric Corporation, New York, N. Y.

For this purpose all other equipment has been largely superseded by the electric shovel, which is usually of 4 to $4^1/_2$ cubic yard capacity. These shovels are capable of loading up to 5,000 tons of ore per 8-hour shift. Modern equipment is of the full revolving type, the majority of which are operated by d-c motors on all motions. Power for the motors is furnished by a variable-voltage motor generator set which greatly facilitates control and ease of operation. A $4^1/_2$ cubic yard full revolving shovel is illustrated in Figure 1 and a typical schematic diagram of main driving motor, generators, and individual drives is shown in Figure 2. The a-c power supply is conveyed to the shovel through flexible 3-conductor cables, which are referred to later. Amongst the other electrically-operated equipment used in open-pit mining is the churn drill, which is used for drilling holes in preparation for blasting. Power supply for the shovels, churn drills, and other equipment in the mine, is usually brought to the pit edge at voltages from 6,600 to 13,800 volts over the primary lines, and is then transformed at one or more points to 2,300 or 4,100 volts for shovels, and 440 volts for churn drills. From the secondary line, which generally encircles a large portion of the pit, distribution is made through portable switch houses for the shovels. These switch houses contain a suitable circuit breaker and relaying apparatus for shovel and cable protection. A similar distribution center known as a churn-drill house is used to provide power for the churn drills. These are fed also from the 2,300-volt secondary line and contain, in addition to disconnect devices, a transformer of sufficient capacity to operate two or three churn drills. The former are usually transported from one location to another by means of a boom and the latter, which are usually mounted on skids are moved about by caterpillar tractors as required. A typical shovel-switch house diagram is shown in Figure 3, which also illustrates the diagram for a churn-drill transformer house. Shown also is a grounding scheme which is discussed in detail later.

Because of the importance of maintaining power service to the shovels, a brief description of the cables used, and methods of protecting same, as well as the operating personnel, is included.

The capacity of each car is 70 tons. Churn drills appear on bench above the shovel

Figure 2. Typical single-line schematic diagram for variable voltage shovel control

These cables are usually 3-conductor, insulated with a high grade of rubber insulation and jacketed with a tough outer covering of Neoprene or other abrasion resisting compound. A metallic sheath is frequently employed over each conductor, which serves the purpose of distributing the electrostatic stresses and can also be used for ground connections. In addition, three ground wires are sometimes incorporated in the interstices, thus providing ground-return conductors of considerable capacity. In most open-pit mines, due to the nature of the terrain, it is difficult to provide proper grounding at the shovels. If this is not done, severe electrical shocks may be experienced by the personnel in case of a ground on the shovel apparatus or wiring, when entering or leaving the shovel or touching any part of the framework while standing on the ground. In the case of grounded neutral power-supply systems, protection is obtained by connecting the ground wires to the shovel frame and to the neutral of the transformer bank and/or low resistance ground sources near the switch houses or power lines. In the case of delta-connected power transformers, which are normally ungrounded, excellent protection can be obtained by application of a 3-phase so-called zigzag grounding transformer, which provides a low-impedance ground path for return currents. If the neutral thus obtained is carried on the distribution lines, through the switch houses and ground wires in the cables to the shovel, this method possesses another advantage in that selective relaying of the parallel feeders can be readily obtained in addition to limiting the rise of voltage on the shovel frame in the event of a ground fault in the shovel equipment. A schematic diagram of equipment designed for this purpose is shown in Figure 3. It will be noted that a resistor is connected between the grounding transformer neutral and ground connections. The purpose of this is to limit the amount of ground current which can flow into any fault and is a desirable feature of this system. For normal application the maximum current which is allowed to flow in a ground fault is limited to values between 12.5 and 25 amperes.

Transportation

At most properties, the usual practice is to locate the reduction works or plant for milling the ore as close to the pit as possible to reduce the cost of transporting large tonnages of ore, of which the greater part is discarded after separation. The type of transportation used between the pit and the mill depends on several factors, such as the topography of the ground, length of haul, and tonnage to be handled. Where large tonnages are handled, if it is practical to do so, rail haulage is usually employed, and in many modern systems these are electrified. Other forms of transportation are truck haulage, hoisting, or a combination of any of these. Types of locomotives used on pit haulage systems include steam, diesel-electric, trolley or third-rail straight electric, and trolley or third-rail combination locomotives with auxiliary power, for operation on benches supplied by storage batteries or diesel engines. Because of lack of sufficient space, description of these systems must be omitted.

Figure 3. Diagram showing main circuits of shovel and churn-drill switch houses and special grounding transformer

Crushing and Conveying

After transportation from the mine the ore is delivered to the crushing plant, where it is reduced to about ten inches in size by passing through the primary crusher. These may be of the jaw type or the gyratory type, but in either case, call for the application of electric motors usually ranging from 300 to 500 horsepower capacity and especially designed for rugged and continuous service.

In the larger sizes, wound-rotor motors with pedestal-type bearings are frequently used because of the importance of maintaining uninterrupted ore flow. In such cases the starting equipment for 2,300-volt motors often consists of a heavy duty circuit breaker with automatic acceleration. This, together with other electric equipment, is best located in a dustproof

Figure 4. Plan (a) and elevation (b) of typical dual conveyor drive

Figure 5. Typical relay protection curves for 300-horsepower crusher motor

control room or substation within or near the primary crusher building and provided with remote controls extending to the control desk on the operating floor. At the control desk are also located the "Start" and "Stop" buttons for the primary-crusher lubricating system and other necessary auxiliaries together with emergency "Stop" buttons and indicating lights for the feeders and conveyors on which the output of the crusher is carried.

From the gyratory crusher the ore is discharged onto conveyors, which deposit it in storage bins of sufficient capacity to adapt the intermittent operation of the primary crushing plant to the continuous operation of milling. From the storage bins, the ore is conveyed to the secondary crushing plant, where it is further reduced in size by a series of cone or roll crushers, or a combination of both, and again conveyed to the storage bin at the concentrator. From this it is seen that all of the ore is handled by belt conveyors from the primary crushing plant up to and into the storage bin at the concentrator. In many of the larger plants these belt conveyors must be built to handle large tonnages which frequently involve the use of large and unusual driving motors. These conveyors almost invariably are of considerable length and designed for a maximum incline, without backward slippage of rock, to keep the length as short as possible. Frequently the loads imposed are such that in order to transmit the power required for the conveyor, a single pulley drive becomes excessively large, and to overcome the disadvantages and cost of enormous head pulleys, the dual conveyor drive has been developed. This consists of a pair of driving motors, referred to as the primary and secondary drives, respectively, which drive two independent sheaves, located to obtain a maximum pulley wrap by the belt. By proper design the total stress in the belt is thus reduced and consequently the life is extended and cost reduced. For this type of drive, the motors are of different sizes, with the primary motor two to three times larger than the secondary motor. This combination results in a lower slack-side tension than is otherwise possible and consequently less total tension when the conveyor is fully loaded. An interesting feature of these drives is that although pulleys of the same diameter are used they cannot be driven at exactly the same speeds, as the slight difference in slippage between the two pulleys, present with any belt drive, would defeat the purpose of the dual motor arrangement and result in disproportionate loads being carried on the motors and much wear and tear on the belt. A plan and elevation of such an arrangement showing the driving motors and pulleys is shown in Figure 4(*a*) and (*b*).

The slight difference in speed referred to previously may be compensated for in several ways, but one successful method is to use slip-ring motors having the same speed-torque characteristics and including a permanent slip resistor in the secondary side of the secondary driving motor. If this resistor is equipped with taps an initial adjustment can be made to insure correct division of power between the two motors, which will then divide the load in proper proportion over range of loadings imposed on the conveyor. Smooth and positive acceleration on both motors is insured by providing several accelerating points, controlled automatically from a master panel which keeps both motors in step throughout the acceleration period.

Amongst other noteworthy features is the system employed to prevent any series conveyor from overloading the preceding conveyor or the equipment which it is feeding, in case of accidental stoppage of the latter. This is done usually by interlocking all conveyors in series with each other and with equipment they may be feeding, by a combination of electrical and mechanical interlocks so arranged that if a crusher stops for any reason the conveyor or conveyors feeding it are in turn stopped to prevent burying the equipment in ore.

In general, the primary crushers are usually driven by slip-ring induction motors, while the secondary crushers may be driven by slip-ring, squirrel-cage, or

synchronous motors. On heavy drives of this type which are subjected to very severe service and abuse it is necessary to incorporate adequate relay protection so that burning out of the crusher drive motors will not result from repeated attempts to start a choked crusher. This protection is usually obtained by a combination of relays designed to protect the motor against prolonged high-inrush currents, prolonged overload or repeated closing of circuit breakers to a stalled motor. A typical relay protection curve for these drives is shown in Figure 5. Inspection of these graphs shows that each element or relay protects the motors under different conditions which can frequently occur. At first glance it may appear that the thermal relay protection is not needed because the induction-type overload relay will remove the motor from the line in case locked rotor current persists. In case of a choked crusher, however, repeated attempts may be made to start, thus burning out the rotor in a short time unless this contingency is guarded against. It will be noted that in the specific case shown in Figure 5 that locked rotor current will cause the induction-type relay to trip in two seconds. However, this relay resets instantly and the starting could be repeated indefinitely. On the third attempt, however, the elapsed time has reached the zone covered by the thermal relay, which therefore trips the motor breaker and prevents restarting in accordance with the resetting curve shown also in Figure 5. This enforced delay gives the motor rotor time to cool before attempts to start it can again be made.

Concentrating

From the concentrator ore bins the crushed sulphide ore is fed to the grinding mills, in which wet grinding is employed. They are continuously charged by automatically-controlled feeders and conveyors which deliver ore into the mill at a predetermined rate of feed. The output of the grinding mills, of which the most commonly used type is known as the ball mill, then passes successively through the classifiers, flotation section, and filter plant. The oversize from the classifiers is returned to the input of the ball mill as feed, while the overflow containing the values and the fines are carried in launders to the first of a series of flotation machines. By the addition of certain reagents at this stage, and by suitable agitation, the values are recovered in the form of a froth, while the sands are depressed and carried away to the tailings disposal area. From the final flotation sections, the concentrated ore, now containing approximately 30 per cent copper, is carried by launders to thickening tanks, where the water is reclaimed and the thickened concentrate transferred to the filter plant. In the filter plant the concentrate is passed through mechanical filters which remove most of the water, leaving the concentrated and finely-ground products as filter cake.

It is in the concentrator proper that the bulk of electric power is used, and which calls for a great deal of ingenuity on the part of the designers in distributing comparatively large amounts of power in so crowded an area. An idea of the problems involved may be gained when it is realized that in a concentrator with a capacity of 25,000 tons of ore per day, some 20,000 kw is utilized. The largest single users of power are the ball or grinding mills, the largest sizes of which are driven by 800-horsepower synchronous motors, each of which drives a mill handling from 1,500 to 2,000 tons of ore per 24-hour day. As each of these motors constitutes a considerable load, it is advantageous, providing the main substation can be located near the center of the load, to supply each motor through an independent feeder controlled by circuit breakers of sufficient rupturing capacity to handle the short circuit current of the system. The motors are designed for full-voltage starting. Thus space and cost saving is realized by utilizing the feeder circuit breaker as the motor starting switch. Such switchgear must be of rugged construction, capable of continuous operation and of frequently starting a fully-loaded mill which requires a starting torque of approximately 175 to 200 per cent. This equipment is provided with remote control stations conveniently located on operators' platforms throughout the mill length, the switchgear for it being located in a separate air-conditioned control room whereby maintenance is easily carried out and the equipment is protected against fumes, moisture, and dust. Each of the switchgear cubicles is equipped with relaying equipment, varying somewhat with the purpose of the individual feeder. Protection for the ball mills consists of two sets of induction relays which give protection against feeder or motor short circuits, starting and accelerating, and continuous overloads. A typical graph showing the protective relay curves in this application is shown in Figure 6. Comparison of this curve with those of Figure 5 indicates the difference between the two types of protection. In the latter case the service is such that motors are no subject to overheating from repeated attempts to start under locked rotor conditions, therefore relays of the induction type, which reset instantly, give the required protection. It has been found advantageous to furnish power to such circuits from a Y-connected grounded transformer bank, particularly where outgoing feeders are also connected to the same bus. The advantage is that a sensitive ground relay can be added to each circuit-breaker panel, and as many faults start from wire to ground, much faster clearance is obtained than with the 3-phase protection alone.

All of the power distribution in the concentrator for motors 75 horsepower and larger is made at 2,300 volts and power is taken from the same busses to transformers for the 440-volt distribution. In a preceding paragraph reference was made to full-voltage starting and also to the high-starting torque requirements. For these reasons, care must be exercised in the design of the feeder and bus system, to provide for adequate carrying capacity under starting conditions. The system reactance must be considered also when calculations for voltage drop are being made, so that the total voltage applied to the motors during the worst starting conditions may be determined. This is particularly necessary when starting torques in the range of 150–200 per cent are required.

Passing to the flotation section, a great many individual drives are used on the mechanical agitation system, some 300 such motors ranging from 10 to 25 horsepower being required for a 25,000-ton plant. To conserve space and reduce the length of the launders, most modern concentrators are built with all of the equipment grouped closely together, leaving only adequate working space and walkways around the groups of machines. Because of the nature of the process a great deal of moisture is always present, and the electrical distribution, both 2,300 and 440 volts in these buildings, proposes a problem both from the standpoint of room and protection against moisture. All distribution is concealed in the walls, floors, or under floor ducts, and because of the huge quantities of water (approximately three to four tons of water to one tone of ore), being pumped continuously through the plant, adequate provision must be made against possible flooding of ducts and conduit runs. It is desirable therefore to eliminate all conduit runs which start and end at a higher elevation than the main body of the run, and to effectively drain all conduits and cable

trenches. Fortunately, because of the desirability of preserving slopes to aid the solution flow, each section is progressively lower than the preceding one and it is possible to provide trenches with adequate drainage for under-floor conduits and raceways.

It has been mentioned that large quantities of water are required for the flotation process. Approximately 75 per cent of this water is reclaimed and pumped back to the concentrator head tanks to be used again. This involves a number of large pumps with their driving equipment, about which there are no special features except the interlocking and level control systems which automatically pump the water in the required amounts. These controls are also equipped so that failure of one pump will close the starter of a second pump and thus pick up the load.

Smelting

From the filter plant the partially dry concentrate is transferred to the smelter where it is charged into gas, oil or coal-fired furnaces known as Reverberatories. At this point the necessary fluxes required for proper smelting are added, and as the charge is melted down, impurities form at the top of the bath which are later tapped and run off in the molten state as slag. The lower part of the bath is now molten metallic copper and is tapped off as matte into ladles and transferred to the copper converters for further treatment. At this stage the copper contains a large percentage of sulphur and iron. In the converters, air is continuously blown through the copper by a series of pipes, thus burning up most of these impurities. After the proper stage has been reached, the converters are tilted and the copper is poured out and transferred to what is known as a poling furnace, where wooden poles are inserted in the copper to reduce the oxygen content. At the proper stage, the comparatively pure metallic copper is poured into slabs or anodes for further refining.

Although the smelting process is an ancient one, modern production methods have made it possible to handle large tonnages continuously, and the application of electric power to this process is responsible in a great measure for the comparative ease with which enormous quantities of molten copper are handled daily, and for the safety features which allow the process to be carried on at maximum speed and with minimum interruptions. From the moment the molten copper is tapped from the reverberatory furnaces, it is handled by huge electric cranes until it is ready for shipment in the form of billets or anodes.

One of the most interesting features in connection with the electric-power supply to a smelter is that if either the electric-power supply or the air supply to the converters is interrupted, a serious situation immediately arises. As stated before, air is continuously blown through the molten-copper mass in the converters. This is introduced into the lower part of the converter at about 16 pounds pressure through pipes or openings called "tuyeres." Should the air supply fail, molten copper immediately runs into the pipes under the converter, and unless the latter can be tilted quickly the copper cools in the orifices and cannot again be melted out. Apart from the loss entailed by thus ruining the furnaces, the loss of production would be tremendous before new converters could be installed. Every effort therefore is made to insure continuous air supply, and failing that, continuous electric power for as long a period as is

Figure 6. Typical relay protection curves for 800-horsepower synchronous ball-mill drive

Figure 8 (lower right). View showing skipway with primary crushing plant at bottom, hoist house at top

necessary to tilt all the furnaces, thus uncovering the tuyeres and allowing the molten copper to run out before setting.

Several methods have been used to insure continuation of electric power. This is sometimes accomplished by the use of stand-by storage batteries, steam-driven auxiliary generators, or what is known as flywheel motor generator sets. The latter is one of the most interesting applications and has proved to be a very reliable piece of apparatus. Because of their flexibility and ruggedness, d-c motors are usually applied for operating the crane and tilting the converters, so that one or more generator sets are necessary to convert the power from alternating current to direct current. In the design for a smelter, after the final requirements are known, it is possible to calculate the total amount of energy required to tilt all the converters and to move all the cranes which may be handling molten metal, and by incorporating a suitable flywheel in the motor generator set this amount of energy, with a reasonable margin, can be stored mechanically. This is the principle of the flywheel motor generator set, and in practice, if failure of either or both air and electric power occur, this power is instantly available to turn the converters into a safe position and complete any other operations which are necessary under these conditions. In conjunction with the incorporation of the flywheel, specially-excited generators are furnished with voltage regulators designed to maintain full voltage down to as low as 50 per cent of the normal speed. Thus the stored energy of the fly-wheel is utilized while maintaining normal voltage. Control switchgear for the smelter is similar to that used in other parts of the plant except that special provisions are made and controls incorporated so that on failure of converter air, alarms are sounded and all nonessential feeder circuit breakers are automatically opened, thus leaving the energy stored in the flywheel for use on emergency services only.

The crane driving equipment is of extremely heavy duty and rugged design, with safety features intended to prevent damage from accidental or careless operation and to provide safety for the men working in the converter aisle below the ladles of molten copper.

The final application, which is probably peculiar to the copper industry, is the casting wheel drive. When the copper reaches the final stage, it is frequently poured in the form of anodes, molds for which are carried on a large circular wheel, approximately 40 feet in diameter. Continuous casting is achieved as the anodes are cooled by water sprays and removed before the wheel completes a revolution. As each mold is poured from the pouring ladle, which is kept continuously filled by tilting the poling furnace, the wheel is required to start up, turn a few degrees, and come to rest in position for pouring the next mold. As this operation is carried on rapidly, it is absolutely necessary that the wheel stop precisely in the right position, accelerate smoothly, move the required distance and decelerate smoothly to the next stop. Smoothness of starting and stopping is necessary in order to prevent disturbing the still molten copper as it cools during the intermittent movements required to complete a revolution. Control for the casting wheel drive is automatic and usually incorporates a variable voltage system with special means for achieving smooth acceleration and deceleration. Start and stop push-buttons only are located on the operator's platform, the control of acceleration, deceleration, and spotting being inherent in the control equipment design.

Power Distribution

Where available, power for copper mining operations is purchased from public utility systems, but in many cases because of the remoteness of copper ore deposits, it is necessary to build and operate a power plant for the generation of electric power, so that frequently copper mining and milling operations have a complete electric generating and distribution system designed to meet the rather strict requirements of dependability and continuity of operation. In these systems the principles of sound electrical engineering are applied to obtain the desired results. The capacity of the generating plants range from 30,000 to upwards of 100,000 kw and generator voltages range from 2,300 to 13,800 volts. In some of the larger properties duplicate main busses and switchgear are incorporated in the design in order to insure continuity of operation. In addition, it is frequently desirable to lay out the distribution in sections so that the flow of power parallels the metallurgical flow sheet. By these means, serious interruption of power from any cause in one section will affect only a portion of the output instead of shutting down the whole plant. From the main power plant, parallel and adequate feeders are run to the main substations and other points of distribution where the voltage is transformed to that most suitable for the local needs.

In the type of plant described previously, by far the bulk of the power is distributed from the concentrator substation, where it is frequently advisable to divide power between two or more transformer banks in order to provide a measure of flexibility. In large plants it is advisable also to divide the main concentrator bus into one or more sections for the same reasons and in order to reduce the interrupting-capacity duty on the circuit breakers.

From the main outdoor substations, the secondary connections run to the con-

trol substation located in the concentrator building. Because of the large amount of power involved, it is advantageous to install these cable runs in ventilated tunnels to provide easy access and permit frequent inspection. Through these tunnels is also introduced the cooling air for the main indoor substations, thus providing adequate ventilation and cooling of the cable runs. The danger from fire is reduced by installing cable in transite asbestos conduits racked on each side of the tunnel. In addition, fire detection apparatus will instantly shut off the ventilating air in the event of a fire originating in the tunnels.

In the indoor substations, as mentioned before, are located the main switchgear for 2,300-volt feeders and also all of the magnetic starting equipment for the flotation motors and other auxiliary equipment. Because of the concentration of this control equipment, the utmost care must be exercised in properly arranging the banks of the 440-volt control equipment to provide adequate ventilation, accessibility, and ease of maintenance.

The main concentrator substation also frequently houses the feeder switchgear for other parts of the plant, such as the primary and secondary plants, drive houses, filter plants, and pumping stations, so that all of the secondary feeders, which comprise the main distribution, are under the control of one operator at a centralized location.

At many places where these mines are located, severe electrical storms are of frequent occurrence, and this section would be incomplete without a reference to the measures employed for protection against lightning. In many of the localities it has been found impossible to entirely protect the systems against momentary surges from heavy lightning strokes which cause disturbances ranging from tripping out the circuit breakers to very severe damage caused by the destruction of some part of the electric power system or equipment. For these reasons and in common with general practice on power systems, the best results are obtained by providing for very fast tripping of circuit breakers on those circuits which are exposed to lightning. Apart from the installation of adequate surge lightning arresters at every point likely to be affected, disturbances are minimized and better protection is obtained by using a grounded neutral system on secondaries of all transformers feeding the affected circuits. By this means sensitive ground relays can be installed providing instantaneous tripping which will open the circuit with the first discharge from line to ground. Practically all measures for lightning protection are of little value, however, unless adequate grounding is provided at all points where grounds are required for lightning arresters or other apparatus. In heavy lightning districts and dry areas, the practice of driving a few ground rods or carrying a cable down the pole and terminating same in the pole excavation is useless, and the protection obtained thereby is negligible. Damage sustained to equipment connected to distribution lines protected in this manner has been very severe, sometimes resulting in complete destruction of switchgear and distribution transformers. In certain areas of the southwestern United States and in the western portions of Mexico, the problem of obtaining adequate grounds is a real one, and in certain locations this can only be done by drilling deep holes down which a conductor of ample size is dropped and terminated in a suitable copper plate. To insure grounds of a resistance in the order of 10 ohms or less, it is frequently necessary to take additional measures such as filling the hole with charcoal and salt, and providing for a water supply to keep the area damp, or arranging for frequent watering down during the periods when electrical storms may be in evidence. By these means it has been found possible to reduce lightning outages and greatly restrict damage to equipment which was formerly experienced.

Figure 10. Diagram showing main connections of hoist motors

A Brief Description of a Plant in Mexico

During the recent war, the facilities of the Cananea Consolidated Copper Company plant located at Cananea, Sonora, Mexico, were expanded to develop for mining by open-pit methods, a low-grade ore body adjacent to the underground mines which have been operated for many years. In spite of the shortages of material and other difficulties imposed by the war, this low-grade mine was stripped, opened, and the plant constructed in the years 1943–44. A modern concentrator was built, together with crushing and auxiliary plants, the whole constructed entirely by Mexican labor, the mine and plant starting production in late October 1944. This mine and plant were designed for a daily tonnage of 12,000 tons of ore and because of some of the unusual features encountered, a short description may be of interest to the profession.

Cananea, Sonora, is located about 45 miles by road south of the border town of Naco, Arizona, on the east slope of the Cananea mountains. The climate is moderate and very agreeable, but the terrain and location of the ore body presented a difficult transportation problem. After the first locations selected were decided against because of faults existing in the rocky formation, making it unsuitable for the erection of heavy buildings, a site was finally chosen for the concentrator about 500 feet below the mine proper. The completed mill is shown in Figure 7, in which the filter plant appears directly in front of the main building. In the foreground are 250-foot thickener tanks, for the purpose of reclaiming water. From the filter plant the concentrated product is trammed over to the existing smelter and converted to metallic copper in the manner just described. Figure 8 is a view showing the inclined skipway terminating in the primary crusher building, from which ore is discharged by an underground conveyor into the storage bin located in front of the primary plant. In

Figure 11. Concentrator control board

Main 2,300-volt switchgear cubicles

the right-hand lower corner appears the secondary plant, with the conveyor gallery leading from underneath the storage bin. In this same figure, the mine benches appear in the upper left-hand corner.

At this property the problem of transporting the ore from mine to mill presented great difficulties. Because of the rough terrain and the difference in elevation, trucking or railroad haulage was almost out of the question because it would have been necessary to traverse switchback roads over the mountain face. Some of the approach roads necessary for operation of the plant appear in Figure 8. The problem was solved by a special hoisting application in which the functions of the ordinary hoist are reversed and it becomes a lowering operation. This hoist is known as a skip hoist and utilizes two 30-ton skip cars which operate on heavy rails having a gauge of 10 feet. The skipway is constructed down the mountain side with a total length of 1,000 feet and with an incline of approximately 30 degrees. The hoist operates in balance, one car being at the top of the slope while the other is at the lower level. The skipway is provided with three loading stations above the primary plant, and the procedure is to haul rock from the level on which it is being mined to the loading station on the nearest level. Twenty-two yard trucks were used, each carrying a load of 30 tons. After loading the skip it is lowered to the primary crushing plant while the empty car is pulled up on the opposite track. During dumping of the first load the second skip is loaded and the cycle repeated. The hoist system was designed to handle a maximum capacity of 1,080 tons per hour, which assured sufficient capacity to deliver the average daily tonnage in less than two shifts. The skip was required to complete the cycle in 100 seconds. Actual length of run from the top loading station into the dump pocket is 750 feet and the rope speed 860 feet per minute.

A choice of method of lowering was available, the two most attractive for loads of these proportions being regenerative or dynamic. In such installations it is usual to provide a spare motor on important pieces of apparatus which form a single link in the process. In the installation referred to, as both regenerative and dynamic lowering had attractive features, a combination control was designed which is unique in many respects. The hoist was provided with two driving pinions, and the spare motor instead of standing idle was mounted coupled to the hoist at all times and equipped with dynamic braking controls. Normal operation is conducted by the use of the number 1 motor which is regenerative. This has a double advantage in that after the hoist has once been started, the descending load rapidly overhauls the motor and at slightly above synchronous speed power is generated and returned to the line. An additional advantage is that the descending load operates at a constant speed as long as the motor controller is in the full on position, whereas with dynamic braking, manipulation of dynamic controller is required at all times to adjust the dynamic-braking torque to the speed of the rope. On reaching the bottom of the skipway, the skips are dumped by a hydraulic mechanism operating at the side of each track, dumping the ore into the center onto the inclined grisly from whence it slides by gravity into the primary crusher. Because of the necessity for accurate stopping, without loss of time, it was advantageous to stop the skip against solid buffers. Therefore no overshooting is permissible, and a feature of the installation is that safety controls will automatically stop the skip if the operator fails to reduce its speed within a safe stopping distance before reaching the pocket.

A curve showing the torque requirements appears in Figure 9. Both regenerative and dynamic lowering cycles are indicated. In the former case, power is taken from the line for fast acceleration and returned to the line after synchronism is reached, the motor then acting as an induction generator. In the case of the dynamic braking cycle, however, the hoist is accelerated by gravity and a longer time is required. The power generated in lowering is not returned to the line but is dissipated by a bank of resistors.

Referring again to the main driving motors, it is obvious that loss of electric power or failure of any of the control mechanisms would result in the skip running away unless the operator was able to stop it by means of the mechanical brakes before the loaded skip crashed into the primary crushing plant. To guard against this possibility in the case of failure of the regenerative motor, whether due to loss of power or failure in the motor or controls, automatic energizing of the dynamic lowering motor immediately takes place, bringing the hoist to a halt in a very short distance. This second motor is a duplicate of the first or regenerative motor, except that one phase of the primary winding is energized from a storage battery of ample capacity to provide dynamic braking functions. In addition to the usual hoist controls an additional controller was provided, whereby in case of a prolonged outage on the power line, the skip could continue to operate as a dynamic lowering hoist, although at a somewhat longer time per cycle. The schematic diagram of main connections is shown in Figure 10 and a brief description of the functions follows.

As stated previously, safety features to provide against almost any contingencies are included. Referring to Figure 10, starting is accomplished by advancing number 1 controller from the off position, which closes the forward contactors designated *LF*. The controller is equipped with eight positions, the last of which is the full-speed or full-torque position. To avoid extremely heavy electrical or mechanical shocks, the controller is therefore notched up as the hoist accelerates until in the full-open position maximum regenerative torque is obtained. Should the operator fail to advance the controller to the full-open position by the time the hoist has reached synchronous speed, a runaway would be liable to occur because of insufficient torque to restrain the descending load. However, motor number one is provided with a pilot generator which generates a voltage proportional to the speed. Through a rectifier indicated

in the circuit diagram, its voltage is opposed to that of the storage battery through voltage differential relay coils *IMT*. At about 95 per cent synchronous speed the pilot generator neutralizes the battery voltage and causes relays to drop out, which compel the secondary contactors into the full-torque position, thus restraining the load to a descending speed corresponding to "slightly above" synchronism. Adjustment of the drop-out point is made by varying the resistor across the generator output.

In the event of failure of line voltage, relay *ACLV* loses its energizing power and through the contactors located in the interlocking and transfer control cabinet initiates closing of the dynamic braking contactors *M* causing the dynamic lowering motor to take over at a predetermined restraining torque, holding the hoist to a low speed until the operator takes control by means of the dynamic lowering controller. As stated previously, both motors 1 and 2 are permanently geared to the hoist. The speed indicating generator, which is driven from the latter, is also equipped with overspeed contacts. In case of excessive speed, these contacts are opened and in turn open the circuit of the low-voltage relay *ACLV*. When this occurs, by means of interlocks, not only dynamic braking is applied but also the mechanical brakes of the hoist are applied.

Although the function of the hoist is essentially lowering, motor number 1 is equipped with forward and reverse control to permit moving the skips against the grade in case the necessity arises and to permit cable length adjustments. The hoist is also equipped with a standard Lilly overspeed governor, but because serious damage and loss of life might occur should the hoist run away, a further safety feature is incorporated. This is accomplished by means of a so-called "speed trap" installed on the trackage. At the point where deceleration of the load should be well under control, if for any reason the operator has failed to reduce speed when approaching the dump pocket, the design of the speed trap is such that this is detected within a few seconds and emergency dynamic braking is applied. If the speed of the hoists is still too high on emerging from the speed-trap zone, mechanical braking is also applied to the hoist, the combined effect of the dynamic and mechanical brake rapidly bringing the skips to a stop. In addition to the foregoing an emergency stop button is located in front of and within easy reach of the operator. In case of emergency it is only necessary for him to give it a light blow to set all emergency braking. In case of cable breakage the skip will no longer be under control but will be stopped by fast-acting clamp-type brakes which grip the rails. These brakes are operated by release of the cable tension.

Distribution in the concentrator was made in a manner similar to that outlined previously under "Concentrating." The main indoor substation was located under the ball-mill floor on a level with the flotation floor, ample room being provided for operation and maintenance of all the equipment housed therein. Completely enclosed metal-clad switchgear was used in all of the substations. Part of the concentrator control board is shown in Figures 11 and 12. A view of the ball mill section of the concentrator appears in Figure 13. One of the 800-horsepower synchronous motors appears at the left-end of the spiral classifiers. In this illustration can be seen also the inclined conveyors carrying the ball mill feed which is controlled by automatic conveyor scales which register the weight and control the rate of feed as it passes over the conveyor. Control for the ball mills and other drives on this floor are located on the operating platform at the rear of each ball mill. Note the absence of power wiring or switchgear in this area where all available space is required for access to and operation of the grinding equipment.

The concentrator substation is located directly below the ball mill floor. Power for the concentrator is brought from the outdoor substation through a tunnel which runs behind the control room. This tunnel serves for distributing power to the ball mills, classifiers, and so forth, located on this floor, and in addition is used as the main air duct for ventilating and cooling the control room in which are housed the d-c motor generator sets as well as the main and secondary switchgear. Proper and adequate ventilation of control rooms, particularly where located in centers of buildings, is necessary for this type of plant, and is a feature of modern installations. In addition to carrying away the heat generated by the rotating equipment, transformers, and so forth, it serves the purpose further of keeping out the moisture laden air, which is always present in the grinding and flotation sections. The main control room is

Figure 12 (left). One end of concentrator control board showing part of the 440-volt distribution board and motor-generator sets for crane operation and synchronous motor excitation

To avoid disturbances in the latter circuit the two d-c busses are normally segregated

Figure 13. View of ball-mill section

Figure 14. Power distribution one line diagram of main connections

ventilated by a 25,000-cubic foot blower which maintains a positive pressure in the room at all times, thus preventing the entrance of moisture and dust-laden air. It serves a further useful purpose in that warm air from the control room is forced through the conduit and duct runs emanating from the substation, thus tending to disperse moisture which would otherwise collect.

With reference to the power distribution as a whole, this was designed in accordance with the methods outlined in the preceding paragraphs, with the exception of a few departures for special reasons. Figure 14 shows the schematic diagram of the power plant and the distribution system.

It should be noted at this point that power for the previous operations was supplied from an existing power plant which was however of insufficient capacity to supply power for the low-grade ore project. Due to the exigencies of the war, a new generator was out of the question and it was necessary to extend the power house, utilizing a 10,000-kw generator allocated by the War Production Board. As this generator alone could not furnish all the power required for the new project it became necessary to interconnect the new and old systems. In any case, this would have been desirable because in the case of a failure of any unit, emergency power could be obtained from the other system.

Because of inherent short-circuit capacity limitations, the new plant bus could not be directly connected with the existing one and a limited link was established by the use of two 2,500-kva transformers. It will be noted that the auxiliaries for the new unit are fed from an extension of the existing 2,300-volt bus. This permitted the maximum output of the new generator to be used for the new project with a very limited exchange of power between the two systems. Because of the unusual voltage of the turbogenerator allocated, it was necessary to incorporate a step-up transformer between the generator and the 11-kv bus. This, however, served the purpose of increasing the system reactance, thus reducing the duty on the main oil circuit breakers throughout the plant.

Indicated on this diagram are the short-circuit currents at various points in the system and these were adjusted by proper choice of transformer impedances, so that the capacity of the circuit breakers used on the busses in the substations is of lower rupturing capacity than would otherwise be required.

An interesting result of the application of regenerative lowering to the hoist described before is the fact that from 30,000 to 40,000 kilowatt-hours per month were returned to the power house in excess of the hoist demands. This resulted in the transportation of the ore from the upper skip level into the surge bin preceding the secondary plant at no cost for power. In other words, the crushing and conveying of the ore up to this point was accomplished by power derived from the operation of the hoist.

From the power house, bus feeders at 11,000 volts are carried by overhead lines. Some of these, notably the mine and Del Rio feeders extend a considerable distance and are exposed to severe electrical storms. In the case of the main pumping station located some 13 miles away, a 2-circuit line was installed because of the importance of a continuous water supply. In addition to other measures to insure reliability in operation considerable attention was devoted to lightning protection. The design for the 11-kv line included a static or ground wire, adequately grounded at frequent intervals, and the installation of high-capacity lightning arresters both at each end and at intermediate points. That this protection is justified is shown by the excellent performance compared with lines without static wire or properly rated lightning arresters. From the main pumping station, 2,300-volt feeders are carried in opposite directions to eight deep well pumps distributed along the bed of the Del Rio, extending about two miles in each direction. These lines were similarly protected with surge lightning arresters at each pump house.

Similar construction was used for the mine line, with the exception that in places where the greatest exposure appeared likely, double static wires were used, this measure having proved effective in such terrain and reducing outages caused by lightning to a minimum. As stated previously in this paper, the importance of low-resistance grounds cannot be overstressed, and the co-ordinated lightning protection system as a whole resulted in these lines continuing to give service when others not so protected were incapacitated.

It will be noted by referring to Figure 14 that the transmission lines emanating from the 2,300-volt bus at the concentrator substation are operated from grounded neutral transformers, thus obtaining a quick clearance on ground faults.

In conclusion, an interesting point about the 12,500-kva generator is that ground protection of its windings and the primary of the step-up transformer could not be obtained by the usual resistance method of grounding because of the large physical size and cost of the resistors with a machine of such a low voltage. In consequence, a modified potential method of grounding was used, which is designed to trip the main-generator oil circuit breaker after a very short time delay at the start of a fault to ground in either the generator or step-up transformer primary windings.

Discussion

R. S. Sage (General Electric Company, Schenectady, N. Y.): The comprehensive paper presented by the authors is a notable contribution to the literature now in existence on this subject. The interesting treatment of various operations involved in the modern open-pit copper mine should be of interest alike to the mining industry and to those engaged in the application of electricity to this basic industry.

The gradual substitution of electric and other forms of haulage for the steam locomotive in several of the large open-pit operations has resulted in operating benefits scarcely matched in any other field of modernization. For example, it is reported that the recent substitution of the electric trolley type for the steam locomotive by one large company has resulted in an increased ore output of more than 20 per cent. This has come about by the greater availability and increased reliability of the electric locomotive.

For essentially the same reasons, large operating economies and increased tonnages have followed the replacement of the steam shovel by the modern d-c drive caterpillar-mounted revolving shovel. A not insignificant portion of the benefits derived in this case are due to the greatly reduced maintenance expense. Reliable figures in some quarters indicate a ratio of 4:1 in favor of the electric shovel. It may be well to point out, incidentally, when referring to Figure 2 of the authors' paper, that the series fields on the adjustable voltage generators are wound differentially with respect to the separately excited and self-excited fields. This combination results in a characteristic admirably adapted to a machine of this nature in that the dipper may be stalled in the bank with a minimum of shock to the shovel structure and to the driving machinery, by limiting the current which the motors can draw, to a definite and predetermined maximum value.

It is important, as the authors pointed out, to carefully co-ordinate the type of overload protection for the various machine drives, used in the concentrator, in accordance with the operating load conditions, so that the maximum of protection is afforded without

unnecessary removal from service by the tripping of overload relays.

The authors have well presented the advantages of d-c dynamic braking for the ore skip hoist. There seems to be a revival of interest in this type of control for wound rotor induction motors which operate hoists involving a considerable amount of operation with overhauling loads. The economies realized in power consumption and the ability to operate satisfactorily at reduced speeds, when handling heavy down-going loads, justify serious consideration to this well known, but not too frequently applied, control system. While especially adaptable to unbalanced slope hoists, this type of control has also recently been applied to very deep balanced shaft hoists, in which the down-going rope presents a heavy negative load, not otherwise effectively contended with where a wound-rotor drive motor is used, unless plugging is resorted to.

Victor Siegfried (American Steel and Wire Company, Worcester, Mass.): This paper is very interesting and presents a clear concept to the uninitiated of the electric equipment involved in mining uses. From the stand-point of a cable manufacturer, I am very much interested in the usage or load factor of the equipment on the shovel fed by trailing cables.

The current carrying capacity of these trailing cables involves a reasonable guess as to the likelihood of some of the equipment not being in use at the same time as other. This is indicated in part by the rating of the motor generator set, with a motor of 275 horsepower and connected generator capacity of 240 kw or 320 horsepower at 100 per cent efficiency, in the example cited. This infers a load factor of approximately 70 per cent if conversion efficiency is 90 per cent. A growing tendency to use smaller cables for economy of cost or size or for greater storage capacity of cable on the reels indicates need for caution in the application of such a load factor. It is a matter of concern lest cable designers and equipment designers use the load factor in an optimistic manner and use too small cable for the actual loads encountered, or require cables to run hotter than is intended. The cable industry would like to have the authors' estimate of a good load factor figure for open-pit mining operations.

S. F. French and H. Speight: This will acknowledge the comments presented by R. S. Sage, in which the writer has ably pointed out several interesting phases which were not covered by the authors.

It is our assumption that in the paragraph in which reference is made to d-c dynamic braking for the ore skip hoist, Sage also intends to include the application of regeneration for negative descending loads. In the specific application cited, both regenerative and dynamic braking are used in normal operation of the hoist although the authors omitted this explanation in the original article. It will perhaps clarify the matter to state now that at the moment the controller is moved to the off position, a percentage of the total dynamic braking available is automatically applied, reducing the duty on mechanical brakes and retarding the descending load until it is further slowed by the operator.

In his discussion, Siegfried brings up some questions which introduce problems involving many factors, and because of this it is difficult to present the answer in a brief and concrete form. The question of cable ratings for such application is of a very controversial nature and it is doubtful whether a fixed load factor can be assigned to suit all conditions of operation. To illustrate the range of current values that may be obtained on the type and size of equipment, of which the illustration is typical, the motor generator set, through which power is furnished to the shovel is rated 275 horsepower, 220 volts, 3 phase. Full load amperes of this motor are 64, with a locked rotor value of 460, and it is obvious that values of current between the no-load value and the locked-rotor value may be imposed frequently with the shovel digging in rock. The characteristics of the hoist and crowd generators, however, are designed to limit the torque output and therefore the load which will be imposed on the motor and line. In practically all cases the greatest load will come in hard digging, when both the hoist and crowd motors are near their stalling points. In both instances we can assume a maximum torque on the hoist and crowd motors of approximately 200 per cent rated torque, which at 85 per cent combined efficiency would require approximately 530 horsepower from the motor, and this value can be taken as the maximum short-time peak, as no other motions are involved under these conditions. Assuming voltage to be maintained, the motor amperes will rise to approximately 145. Neglecting the consideration of voltage drop which may or may not be involved, depending on the system, conservative practice would indicate that a number 2 rubber-insulated rubber-sheath 3-conductor cable should be used. This cable has a rating of approximately 88 amperes continuous in air with a copper temperature of 60 degrees centigrade.

The foregoing is, of course, based on 40 degree ambient, and if conditions are such that higher air temperatures are frequent, proper allowance must be made. It will be noted that such a cable would have a continuous rating of about 135 per cent of rated motor capacity. Although the stalled digging current may be frequently attained, all equipment of this type is subject to alternations between the heavy loaded and the no-load condition, and such a cable as described, employing one of the high-grade rubber compounds will be found to give excellent service.

As stated previously, no general rule can be made, but each application must be considered individually because of the varying factors, such as: temperature, type of service, and mechanical abuse to which the cables are naturally subject. We believe the general tendency to use a smaller cable is largely due to another factor, namely—the greater convenience and flexibility of the smallest cable which will provide trouble-free and economical use.

Electrification of Petroleum Pipe Lines

M. A. HYDE
MEMBER AIEE

THE ADVANTAGES of pipe lines for the overland transportation of petroleum and its refined products, while known to the industry for many years, were most strikingly demonstrated during World War II. In that critical period of transportation shortage, existing and new lines formed a vital part of an integrated transportation system to make petroleum available where needed. During the years 1941 to 1945 inclusive, the mileage of trunk crude oil and products lines in the United States increased by about 13,000 miles, to a total of 85,000 miles, not including some 57,000 miles of gathering lines.

Naturally, some of these facilities have undergone modification to meet changed postwar needs. Among these are the 24-inch crude line and the 20-inch refined-products line, familiarly known as "Big Inch" and "Little Big Inch."[1,2] These two lines delivered as much as half a million barrels per day of crude oil and refined products from Texas to the New York and Philadelphia areas. They did this with electric power, requiring only $0.05 worth of electric energy to move each barrel over the 1,400-mile course. These lines are now in service as natural gas carriers. They are being equipped to deliver 433,000,000 cubic feet per day of much-needed Texas gas to the eastern areas. And in the performance of this task electricity will play a preponderant part. For driving centrifugal compressors on this project, 1,250-horsepower motors available from the 20-inch products line will be supplemented by larger motors now under construction, to a total of at least 117,000 horsepower in electric drive.

With all the additions made during recent years present pipe line facilities are inadequate. New lines are planned years ahead and their construction is proceeding at a rate limited only by the availability of steel pipe.

Table I, which summarizes an estimate[3] of the pipe line construction program for the 1947–1951 period, shows that projects completed, under construction, and announced, will add to existing pipe line facilities a mileage equivalent to more than once around the world.

There is a significant increase in the use of pipe lines for the transportation of petroleum products from the refining centers to important marketing areas. Numerous products lines have thoroughly demonstrated this method as the economic way of handling large shipments of liquid petroleum products on overland routes to centers of stabilized demand. The result has been consistent growth in such facilities and it is not difficult to envision future distribution of refined products by pipeline to every sizable inland community.

Advantages of Electric Power

In recent years pipe-line projects in the United States have shown a marked trend toward electric power. This is due to constantly increasing availability of electrical service and to widening appreciation of the advantages of electric power from the standpoints of low investment in station equipment, low maintenance and attendance costs, reliability, and effectiveness of control.

Motor Applications

The pumps used on crude oil and products lines are of both reciprocating and centrifugal types. Reciprocating pumps may be driven by squirrel-cage induction motor through gear or other means of speed reduction, or by low-speed synchronous motor applied directly to the pump-pinion shaft.

Except when pumping high-viscosity oils particularly through smaller lines, centrifugal pumps are used predominantly for crude and products lines, because of lower initial cost, smaller building space requirement, mechanical simplicity and inherent limitation of the pressure developed in the unit. Drive is ordinarily by squirrel-cage induction motor, coupled, at 1,800 rpm or at 3,600 rpm on 60-cycle power supply. In selecting the speed it is necessary to consider the combined cost and performance of motor and pump for the specific requirement. The pump may be less expensive at 3,600 rpm but the opposite is usually true for the motor.

In gas transmission, the use of centrifugal compressors driven by squirrel-cage motor is becoming more common with the development of suitable compressors. The major installations to date operate at 3,600 rpm with coupled drive. Step-up gear drive to compressor speeds above 3,600 rpm have been used in other applications and are a future probability in gas transmission.

The applications just outlined seem at first glance to be so simple as to warrant no further discussion. That would be true if pipe lines were always operated at maximum capacity, at uniform capacity throughout the line length, handling fluids of constant viscosity and specific gravity. For these conditions the constant speed motor would be ideal. But in crude and products lines, particularly modern lines with no "breakout" tankage at the booster stations, problems are introduced by operation at part capacity, by deliveries made at intermediate points, by variations in the pressure-flow characteristic of the line due to change in viscosity of the pumped liquid, and by

M. A. Hyde is industry engineer, Westinghouse Electric Corporation, East Pittsburgh, Pa.

The author acknowledges contribution to the portion of this paper dealing with pipe-line and pump characteristics by H. B. Britton, chief engineer, Middle East Pipe Line Company, A. Hollander, consulting engineer, Byron Jackson Company, and W. J. Curry, chief dispatcher, product pipe line department, Shell Oil Company.

variations in operating pressure when handling liquids that differ in specific gravity and viscosity.[4]

To meet these variations in operating conditions, and at the same time to hold the pressures along the line within the limits established by economic design, imposes the necessity of controlling the station output pressures. Speed control of the pumps is an obvious answer, but by and large it is not the economic one.

Line Operation at Partial Capacity With Constant Speed Pumps

Operation at partial capacity is practical with constant speed motors throughout the line, if the number and size of pump units is advantageously chosen. Usually the pressure to produce the designed flow through the line is applied at several stations along the line rather than at a single station at the source. The total applied pressure is the sum of the several station pressures, and the latter are held to values economical from considerations of pipe and equipment design.

Consider a pipe line over level terrain, with four stations, *A*, *B*, *C*, and *D*, each consisting of a single constant speed pump developing, at full flow, pressures *A1A2*, *B1B2*, *C1C2*, and *D1D2* as shown in Figure 1. The pressure gradient line between stations is *A2B1*, *B2C1*, *C2D1*, *D2E1*.

Now consider operation of this pipe line at reduced capacity. The total pressure applied to the line varies approximately as the 1.85 power of the flow, and the hydraulic horsepower as the 2.85 power of the flow. Therefore in a period when the line is required to transport less than full capacity, it is most economical to operate continuously at the lowest flow that will deliver the required throughput over the period, rather than to operate at some higher rate for a portion of the period and shut down for the remainder.

Figure 2 shows a typical pressure-flow characteristic for the pipe line represented in Figure 1, along with typical pump characteristics for the four identical stations operating in series to deliver 100 per cent pressure, resulting in 100 per cent flow. Shown also is a line representing the approximate power consumption at various flows for each pump operating.

The pipe line may be operated at reduced capacity by shutting down stations *B* and *D* leaving stations *A* and *C* in service, operating at a flow of 73 per cent and pressure of 54 per cent. Stations *A* and *C* are now operating at slightly higher pressure than they did when the line was carrying full flow. The pressure gradient in Figure 1 becomes *A2C1*, *C2E1*. The power per barrel per day is $25 \times 86 \times 2/73 = 59$ per cent of that at full flow.

Table I

Project Location	Type Lines	Mileage
United States	Crude oil	7,600
	Products	5,300
	Natural gas	10,900
Outside United States	All	5,200
Total		29,000

A still lower flow rate may be obtained by leaving only station *A* in service, operating at 52 per cent flow and 28 per cent pressure, the pressure gradient in Figure 1 becoming then *A2B1*. The power per barrel per day is $25 \times 75/52 = 36$ per cent of that at full flow.

In practice, ability to operate on these or any partial-capacity gradients is contingent upon the gradient line clearing any local high points in the pipe line. It is also necessary that the maximum pressure at the discharge of any station be within the allowable working pressure established for the pipe, and that the suction pressure at any station be above the low limit established for safe pump operation.

Suppose now that station *C* is out of service and it is desired to operate the line at maximum possible capacity. This can be done by operating stations *A*, *B*, and *D* as shown in Figure 3. At station *B* excessive line pressure is avoided by throttling pressure *B2B3*, also at station *D* throttling is introduced to dissipate excess pressure *D2D3*. The total pressure effective on the line is then equivalent to that of two stations with resulting flow rate and gradient the same as for Figure 1.

Even throttling half the pressure at two stations, the power per barrel per day is $25 \times 86 \times 3/73 = 88$ per cent of that for full capacity operation, compared to 59 per cent for the same flow when stations *A* and *C* are operated without throttling. Of course, power is only one component of the total cost per barrel transported, and the most economical operation is not determined by the minimum power per barrel.

It is evident from Figure 3 that if each station consisted of two pumps in series, then stations *A*, *B*, and *D* could be operated at the same flow rate by taking one unit out of service at stations *B* and *D* instead of throttling the excess pressure at these stations. Subdivision of the total stations pressure into two or more series units also provides operating steps intermediate to those obtainable by "skip station" operation.

This practice has been extended to the employment of as many as three main units of identical characteristic, plus one or more units handling the station throughput at reduced head. A 22-inch crude oil line under design at time of this writing will employ six stations consisting of three full-head units each driven by a 1,250-horsepower squirrel-cage motor. Each pump develops approximately 240 pounds per square inch under rated flow conditions, or 720 pounds per square inch for the three pumps in series. Each station will also include a half-head unit to develop 120 pounds per square inch handling full station flow. Three full units will operate normally, but at times two full units and one half unit will be used, or other combinations. This arrangement makes available seven pressure steps per station, using constant speed motors.

A similar arrangement of constant-speed pumps on a refined products line employs three full-head pumps each driven by a 200-horsepower motor and developing 320 pounds per square inch, in combination with a half-head unit developing 160 pounds per square inch, thus providing seven steps of station pressure with a maximum of approximately 1,120 pounds per square inch at a throughput of 18,600 barrels per day of gasoline. In this case the half-head unit consists of two pumps in parallel, each driven by a 60-horsepower motor. At rates below 12,000 barrels per day, the 60-horsepower units are used in series combinations for more efficient operation.

It is evident that numerous combinations of full-head and part-head units can be laid out to give multiple steps of station pressure. For a given total station capacity there is an economic limit to the extent of subdivision, as reflected in increased total cost of pumps, piping, valves, motors, and control. More than five pumps per station would probably not be justified in any case. The number of different ratings should preferably not exceed two for a pipe line having uniform capacity throughout its length.

With three pumps per station in two ratings, five steps of station pressure can be obtained by installing two full-head pumps and one half-head pump, all operable in series, as shown in Figure 4.

Ten steps of flow may be had by operating these stations in pairs with the pumps scheduled to give pressure steps of one half-head unit per pair of stations. Thus full flow is attained with $2^1/_2$ units in service at all stations. For the first step of flow reduction, stations 1, 3, 5, and so

Figure 1. Pressure gradient for a pipe line with four stations on level terrain

forth, operate $2^1/_2$ units while stations 2, 4, and 6, and so forth, operate two units, an average of $2^1/_4$ units per station, under which condition the effective head is 92 per cent and the flow 95 per cent. The second step of flow reduction is with all stations operating two units, and so on down.

Under this schedule the first step of flow reduction imposes a pressure slightly higher than the normal pressure for 100 per cent flow at stations 1, 3, 5, and so forth, where all pumps are in service but at less than full flow.

The amount of excess pressure is minimized by installing pumps having a relatively flat-head capacity characteristic. It is usually feasible in pump design to hold the pressure rise within 20 per cent from rated flow to shut off. With such a pump characteristic the 10-step schedule outlined before involves a maximum pump pressure of only 103 per cent full flow pressure, this pressure being developed in stations 1, 3, 5, and so forth, and on the first step of flow reduction.

It is evident from these cases that constant-speed pump drives can be adapted to a wide range of line flow rates, providing small increments of flow, and requiring little throttling action.

It is always desirable to operate with minimum throttling, since the throttled pressure represents a proportionate part of the pump input power that is not utilized in the line. However, the station throttling valve under suitable automatic pressure-limit control has been a very useful feature on many pipe lines. The control system commonly employed automatically introduces throttling to prevent a rise of the station discharge pressure above the established upper limit, and introduces throttling to prevent a fall of the station suction pressure below the desired minimum. This control system is also useful for bringing a pump onto the line smoothly. The oncoming unit can be started with the control system set to maintain the previously existing pressure at the station discharge, and then by slowly increasing the discharge-pressure setting, the pressure increase can be made effective on the line very gradually with a minimum of pressure surges.

In shutting down a unit, smooth line conditions are attained by first gradually reducing the station discharge-pressure control setting to the value anticipated without the unit, and then stopping the unit. Automatic pressure-limit control by throttling has contributed on numerous lines, both product and crude, to smooth operation with constant speed pumps, and has prevented many interruptions that would have occurred due to

Figure 3. Pressure gradient for 4-station pipe line with third station out of service

development of pressures beyond the settings of protective shutdown devices.

Constant Speed Pump Operation on Liquids Varying in Viscosity

When the pipe line must handle liquids varying in viscosity, the pressure changes encountered with constant speed motor drive are minimized by using pumps having relatively flat-head capacity characteristic in the normal operating range. Figure 5 shows a typical pump characteristic (*F*) in combination with the pressure-flow characteristic for average operation with oil of viscosity 70 Saybolt universal seconds (SUS) at 70 degrees Fahrenheit, also for viscosity 52 SUS representing summer conditions and for viscosity 115 SUS representing winter conditions. With the comparatively flat pump curve shown, the pressure variation (*a*) is only from about three per cent above to two

Figure 2 (left). Pressure-flow curves for pipe line with four stations, each containing one centrifugal pump

PUMPS IN SERVICE	EFFECTIVE HEAD IN PERCENT OF HEAD AT FULL CAPACITY	FLOW IN PERCENT OF FULL CAPACITY
2-1/2	100	100
2	83	90
1-1/2	65	79
1	45	65
1/2	24	45

Figure 4. Pressure increments for station consisting of two full-head pumps and one half-head pump

per cent below the pressure corresponding to 100 per cent throughput at average viscosity, a range of approximately five per cent. A steeper pump curve such as *G* would have resulted in increased pressure range (*b*) approximately 11 per cent between the same limits of viscosity.

For simplification in Figure 5 pump curves *E* and *F* are shown as unaffected by the change in viscosity. Actually the pumps will deliver somewhat lower pressure as the viscosity increases, reduction in pump pressure being possibly one per cent for the viscosity range applying in this particular case. This narrows correspondingly the range of operating pressures.

Depending upon individual case investigation, it may prove advantageous to install an adjustable-speed supplementary pump to handle full station throughput and deliver an adjustable incremental pressure to maintain the total pressure at the value determined by maximum viscosity, thereby realizing at lower viscosities greater flow than would be otherwise obtained. However, the benefit from this procedure depends upon the slope of the pump characteristic and the viscosity range. In the case of this line, examination of typical pump characteristic *F* in conjunction with the line curves indicates that this procedure would increase the flow by only about one per cent (*c*) for the average viscosity of 70 SUS and by about two per cent (*d*) for the minimum viscosity of 52 SUS. These increases are approximately two and five per cent, respectively, (*e* and *f*) for pump characteristic *G* which has an unusually high slope in the normal operating range.

The conditions here represented are those of a low-viscosity crude, operating in the turbulent flow range. For highly viscous crudes these differences become many times greater and the pipe line flow may change from turbulent to laminar, requiring quite different treatment. Actually the pipe line represented by Figure 5 is being equipped with constant-speed pumps of relatively flat characteristic, three full-head and one half-head unit per station, each station including an automatically controlled throttling valve to limit the station pressures.

Pump Speed Control to Accommodate Variations in Specific Gravity and Viscosity of Line Content

A much greater benefit from adjustable pump speed can be obtained where the line handles liquids of widely varying specific gravity and viscosity. This is usually the case for refined products lines, which are called upon to transport liquids commonly ranging from gasoline to Diesel fuel. The heavier products also generally have higher viscosity, both properties increasing the pressure required for a given flow in the pipe line. Figure 6 shows characteristics for a certain line, based on measured flow rates and pressures, for gasoline having specific gravity 0.74 and kinematic viscosity 0.79 centistokes, and for Diesel fuel having specific gravity 0.855 and viscosity 6.48 centistokes, at 40 degrees Fahrenheit line temperature. At higher temperatures the variation in line characteristics will be less for a given range of products. For combinations of product range and temperature range the variation may be greater.

In Figure 6 the pressure for 100 per cent flow of 0.74 specific gravity gasoline is taken as 100 per cent. Consider that the working pressure delivered by each station is to be limited to 105 per cent for reasons of pipe stress. Consider also that each station has three pumps in units of 1+1+1/2 head, as before, with $2^1/_2$ units in service for 100 per cent flow of gasoline. Then, when the line is carrying diesel fuel the pump pressure with $2^1/_2$ units exceeds the allowable working pressure. Reduction of the station discharge pressure to the established limit may be accomplished by throttling through pressure drop *p1p2*, or by reduction of pump speed. In the case here shown an estimated saving of approximately 12 per cent of the power required for full-speed operation can be effected by reducing the speed of the half-head unit to approximately 52 per cent of its full speed, using either a wound-rotor induction motor or a squirrel-cage motor with hydraulic coupling.

For this application the hydraulic coupling drive, compared to the wound-rotor motor, has the advantage of using a constant-speed squirrel-cage motor which is the simplest type, generally available in explosion-proof construction and requiring the simplest control.

In the case just proposed, with $2^1/_2$ unit operation there could be some further speed reduction of the half unit in order to

Figure 5 (left). Variations in station operating pressure for typical viscosity changes in crude oil carried by line

Figure 6. Application of variable-speed pump in series with constant speed pumps, for handling products varying in specific gravity and viscosity

Figure 7 (left). 1,500 - horsepower open-type squirrel-cage induction motors driving crude oil pumps through fire wall

Pumps are shown in Figure 11

Figure 8. Centrifugal-pump drive by explosionproof motors eliminates fire wall and simplifies station layout

reduce the maximum pressure on the line. However, at some point the performance would come so close to the 2-unit operation that it could not be justified.

If the conditions of operation impose a wider range of line characteristics than shown in Figure 6, the situation can be met by installing all pumps the same in size. Variable speed drive on one pump then provides pressure control on each step of station capacity, with sufficient range to cover the intervals between successive steps.

Due to slip in the hydraulic coupling it is necessary to size the impeller of the adjustable-speed pump to a maximum speed of about $2^1/_2$ per cent lower than the motor speed.

The variable-speed pump should be the final unit in the series, because at fractional speeds it becomes a pump of smaller capacity that should be fed from, rather than feed to, an adjoining full-capacity unit.

An important advantage of this method derives from the fact that in practice, the stations along a line are never exactly balanced even at design flow. Since the line is never on an even grade, the proportion of static to friction head varies between stations, making the unbalance still greater at flows other than the design rate.

Under these conditions it is very desirable to make minor adjustments of the station discharge pressure and this can be done by speed control over a narrow range, at very small loss.

Employing speed control on only one pump per station, the proposed system leads to a simpler and less costly installation than required for speed control on all pumps.

It is evident that each application requires individual analysis, taking into account the range of conditions over which the line is intended to operate and also the range of loading of the pump drives.

Motor Construction

Not only must the motor's operating characteristics be considered, but also the suitability of its construction for the hazard which may exist at the motor location, due to hydrocarbon vapors in the atmosphere.

Many early installations on crude lines employed open motors. Today's preferred practice is to use open motors only if installed in a room separated from the pump room by a tight partition having a seal through which the motor shaft passes to the pump room. Figure 7 shows the motor room in such a station. To prevent recirculation of the exhaust air from the motor room, a duct from the top of each motor frame carries the air stream out through the roof. In a layout of this type it is desirable to keep the motor room under pressure of air drawn from the outside of the building away from the pump room. This is particularly true if the motor-control apparatus is located in the motor room.

The inconvenience of a partition between the pumps and motors and the problem of motor room ventilation are eliminated by installing the motors in the pump room, and the switchgear in a separate nonhazardous location. This requires that the motors be constructed safe for use in hazardous atmosphere. The explosionproof motor is designed for this purpose, and in the squirrel-cage induction type is available in ratings up to 1,250 horsepower at 3,600 rpm. The simplicity and convenience of layout, and the high degree of safety obtained, make this motor the preferred type in modern practice. Figure 8 shows an installation in a products line station, one of 30 stations using motors of this type in ratings up to 900 horsepower.

Figure 9. 2,250-horsepower squirrel-cage motor of inert gas-filled type for operation in hazardous location

Motors beyond the range of explosionproof construction are available in the inert gas-filled type. This form has been built in ratings as large as 2,250 horsepower at 1,800 rpm and is available in even larger sizes. The motor shown in Figure 9 is enclosed in a housing pressurized with inert gas which is recirculated through the windings and a built-in water cooler. Due to its dependence upon a gas supply and a water cooling system, the inert gas-filled motor has thus far been employed only in processing plants, pipeline engineers having preferred other solutions better adapted to isolated locations which are often limited in water supply.

Enclosed, duct-ventilated motors have been used both in refineries and pipe lines, particularly for ratings larger than obtainable explosionproof. In this type of motor, safe air from a location outside of the hazardous area is brought through a duct to the ends of the motor housing and, passing through the motor, leaves the frame at top or bottom through a discharge duct to a remote termination. Such an installation is shown in Figure 10.

A large crude line now under design will employ in each station three 1,250-horsepower and one 600-horsepower motors of this type, 1,800 rpm. In this installation the duct system of each motor

will be pressurized by a separate blower at the air intake, to put the entire system including the motor housing under pressure, causing any leakage to be outward from the duct system, so long as the blower is operating. The duct system will be purged by timed operation of the blower before the motor can be started. The automatic control includes an air-flow relay at the termination of the exhaust duct, arranged to stop the motor upon failure of air flow.

Outdoor submerged vertical barrel-type pumps have been employed extensively for moving products from storage tanks in terminals and for suction-booster service from tankage to pipe-line stations. Some of these are of the stuffing boxless type, using an oil-filled squirrel-cage induction motor submerged in the pump barrel. Recently, installations of the latter type have been made for main line service on small pipe lines.[5]

Motor Starting Equipment

The advantages of the squirrel-cage induction motor include that of requiring the simplest form of starting equipment. Ultimate simplicity is attained when the motors are started on full-line voltage, a possibility that should always be fully explored when the power service is being arranged.

Centrifugal pumps in pipe-line service are ordinarily started with discharge valve closed, to minimize the torque requirement during acceleration. Motors for this service are accordingly designed with low-starting and accelerating torque, in order to obtain low-starting current with good efficiency. As a result the voltage at the motor terminals usually must be not less than approximately 75 per cent of normal, in order to provide a reasonable margin of torque for acceleration. This means that if autotransformer starting is used, the lowest standard tap voltage practical is that of the 80 per cent tap.

Starting conditions are improved if the station capacity is divided into two or more units, an arrangement desirable for flexibility, as already shown.

Motors should be started on full voltage where the drop in station-bus voltage will not impair the operation of other equipment at the station, or where the smaller voltage drop on the high-voltage feeder serving the plant is not objectionable from the standpoint of service to other power consumers on the system. As an indication of the extent to which full-voltage starting has been practiced, this method was used in about half of the stations on the war emergency "Big Inch" line employing three 1,500-horsepower motors per station.

A number of cases have been encountered where power service to a remote station location was available only over a very weak circuit or on a heavily-loaded portion of an existing power system. Here the capacitor has been used to advantage as a means of reducing the lagging component of motor current.[6]

If corrective effect is needed only while a motor is being started, an intermittent capacitor may be employed with control arranged for energizing the capacitor only during those intervals. In one installation of this type, a capacitor capable of delivering 2,000 kilovars at normal station voltage enables a weak feeder to serve a products line station containing two 900-horsepower pump drives.

Where the power rate schedule justifies improvement of running power factor, continuous capacitors are employed, frequently subdivided so that a section may be switched simultaneously with each motor. Such applications have been made in sections as large as 1,400 kva. Three capacitor sections of this rating have been so applied with three 2,000-horsepower motors in a gas-line compressor station on a power supply of limited capacity.

Location and Arrangement of Motor Control

It is common practice to install the motor control remote from the pump room or in a separate room maintained nonhazardous by pressurized ventilation. With this arrangement the control is, in general, of conventional type which is advantageous from the standpoint of convenient maintenance.

Starting equipment for the main pump motors, which operate usually at 2,300 or 4,160 volts, may consist of air or oil circuit breakers, or of contactors in combination with current-limiting fuses. In most main line stations the use of circuit breakers in metal-clad switchgear is justified. Required interrupting capacity is frequently within the 50,000-kva rating of the light-duty class of switchgear, and even in the largest existing stations 100,000-kva interrupting capacity is adequate. Among the advantages of metal-clad switchgear for pipe-line service are ease of installation, safety to personnel, and minimum down-time for maintenance, particularly when air circuit breakers are used.

The auxiliary drives in a pipe line pumping station consist of such items as motorized valves, suction booster pumps, sump pumps, meter-calibration pumps, pump room exhausters, ventilating fans, and compressors for instrumentation air supply. Most of these applications require explosionproof motors. Usually

Figure 10 (below). Duct-ventilated motors in a pipe-line pumping station

Gauge panel, sealed into pump room window, mounts flow recorder, recording pressure controllers, pressure gauges, and temperature recorders actuating temperature protective relays. Console at center mounts pushbuttons and indicating lights in simplified diagram of station piping

the starters are banked in control centers of conventional form in the switchgear room.

A power-distribution layout frequently followed feeds the station bus through a main breaker installed in the transformer substation at a distance of 100 feet or more from the station. Tripping the main breaker clears all circuits on its load side, and for this purpose explosionproof control devices are provided inside the station.

To avoid interrupting essential loads, such as station lighting and control room ventilation, these are served through a separate auxiliary transformer on the supply side of the main circuit breaker. Explosionproof equipment is installed throughout the station on this essential auxiliary circuit. A pressure-actuated relay may be installed on this circuit to sound an alarm and light a warning light upon failure of ventilating air delivery to the control room.

For interchangeability with a common spare circuit breaker, the main circuit breaker may be of the same type as the motor-starting circuit breakers and installed in outdoor metal-clad switchgear. This switchgear may also house the auxiliary transformers and low-voltage circuit breakers for auxiliary power distribution.

Centralized Station Control

One of the prime advantages of electric power for pipe-line operation is that of centralized control to simplify the duties of the station attendant. When its possibilities are fully exploited, this includes the grouped location of pushbuttons for starting and stopping the main pumps, and the automatic sequence operation of motorized suction and discharge valves associated with each pump, also indicating light supervision of the position of principal valves both motorized and hand operated, and light supervision of critical auxiliaries. It also includes alarm and identification in case of functioning of various protective devices. The control station is sometimes built explosionproof and located in the pump room, but is more commonly installed in the switchgear room with a sealed window to afford view of the pump room.

To illustrate one advantage of centralized control, Figure 11 shows a pump installation using manually-operated suction and discharge valves each requiring over 100 turns of the handwheel for complete travel. Figure 12 shows motorized pump valves controlled in sequence with the pump motor and requiring only a single start-stop pushbutton station for the combined unit. The conventional all-steel control desk of a few years ago has been improved by use of a clear plastic sheet for the top surface. This provides greater durability and permits a simplified piping diagram to be applied to the under surface of the plastic, with clear areas at appropriate points acting as light indicator lenses. Using flushtrimmed pushbuttons this desk has no devices projecting from the top surface, minimizing the possibility of false operations.

Figure 13 shows the control desk console for the initial station of a refined products line completed in 1948. This desk provides control and supervision of three main pump units with motorized valves. It includes also indicating light supervision for two motorized manifold header valves, and a number of manually-operated valves in the system incidental to the storage, batching and metering of the several types of products transported through the line. Each storage tank has a booster pump for delivery of its product to the station suction. These tanks are represented on the station control desk, each with a start-stop pushbutton and supervising light. Equipment of this type permits the exacting procedures of products-line operation to be carried out effectively with minimum personnel.

The advantages of centralized control are being realized in modern crude line installations as well. A crude line project now under design will employ six stations, five of which will serve two parallel but separately-operated lines. In each station a control desk will centralize the operations for both lines.

Discussion

W. G. Taylor (General Electric Company, Schenectady, N. Y.): The information in Hyde's paper is a good example of the type

of electrical engineering so necessary in industrial application engineering work. A good electrical application engineer must also be a good mechanical engineer. His success often is measured by the skill with which he uses simple and often standard, or nearly standard, electric equipment to accomplish results which to the layman might seem to require much more complicated design.

In the case of the oil pipe line, the problems of operation are complex, as Hyde very clearly indicates, and the electrical engineer must not only work closely with the pipeline designer, but also have clear and complete knowledge of what is to be accomplished, to be able to recommend a satisfactorily working arrangement of electric drive which will involve minimum investment and operating attention as well as low maintenance expense.

It is a simple matter to start a pipe-line centrifugal pump; but I would like to emphasize the fact that there may be difficulty in accelerating it up to full speed if the engineer does not compare the required pump torque with the available motor torque, and make sure that the starting equipment provides sufficiently high acceleration voltage for the purpose. This problem is tied in closely with the character of the power supply. If the power system is stiff, full-voltage starting of the pump motors can usually be permitted without difficulty. If it is weak, the voltage drop may prevent the use of a reduced-voltage starter, because the resulting motor accelerating torque would be too low to meet the requirements. It is obvious, therefore, that the use of reduced-voltage rather than full-voltage starting equipment is questionable in either case.

Hyde's paper is an interesting treatment of pipe-line pumping problems from a fresh point of view. The basic information which he gives might well be put in more complete tabular form, showing the relation of variable flow, viscosity, specific gravity, and resulting station pressures to the number of pumping stations, the number and size of operating units in each station, and the relative horsepower loads. His explanation of the method of operating multiple-unit pumping stations to give quite a number of available station-discharge pressures, when using only constant-speed motors to drive the pumps, shows the versatility of electric drive without elaborate design or complicated control.

The design of such stations is fundamentally the problem of the designer of the pipe line, but the electrical application engineer plays a large part in making the project a success.

W. H. Stueve (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): The opportunity to review this paper with an idea of offering a discussion is appreciated because my association with the author covers the period of time during which practically every electrified pipe line was installed in the United States.

The author mentions the great increase in pipe line transportation during the war years of 1941 to 1945, and places emphasis on the accomplishments of the Big Inch pipe systems in that period, but he overlooked stating that prior to 1941 the pipe line transportation industry had installed almost 200,000 horsepower of electric motors on their main trunk lines, and that after the 20" and 24" "Big Inch" lines were completed, the total amount of electric prime movers in use totalled 450,000 horsepower. Today, this means that almost one-half of all prime movers required by the oil and oil-product pipe lines are electric motor driven. The sales rate of equipment for this type of service is now about 3 horsepower of electric motors to 1 horsepower of internal combustion engines. The greatest impetus given to convince the oil pipe line builders of the satisfactory and economic performance of electric motors, was the complete electrification of the "Big Inch" system, which contained 26 4,500 horsepower stations and 29 3,750 horsepower stations on the 24-inch crude line and 20-inch oil-products line respectively.

Generally speaking, the part played by the electrical industry in making this capacity of some 200,000 kw available from Texas to New Jersey is not realized by the public, but the private utilities delivered $2^1/_4$ billion kilowatt-hours from January 1943 to August 1945 to the "Big Inch" system, with shutdowns due to power failures of only 15 hours out of 22,870 hours operated, less than $^1/_{10}$ of 1 per cent of total elapsed time. The foregoing could be added to the author's Advantages of Electric Power.

The author under the caption Motor Applications only vaguely hints that electric motors can be used for natural gas transmission and also omits to state the reason why motors are being used in this type of service.

It is true that 84 1,250 horsepower, 3,600 rpm motors, or 105,000 horsepower, originally installed on the 20-inch products line are being installed for direct drive of centrifugal compressors on the "Big Inch" lines to pump natural gas.

The author's paper is supposed to cover only the petroleum pipe lines electrified, but since the natural gas industry is so closely allied to the oil industry, and further, since the use of electric motors for gas transmission opens up an entirely new field for power usage, it was felt that some discussion of the reasons why motors were being considered for gas pumping would be appropriate at this time.

In the past the conventional installation consisted of gas engine driven reciprocating compressors which cost $200 per horsepower and the station spacing (80 to 100 miles) was such that the compression ratio was of the order of 1.8 to 2.0. When electrical centrifugal compressors are used the station spacing can be one-half (40 to 50 miles) resulting in compression ratios of about 1.3 and savings in power equipment of about 30 per cent in total power required. The electric driven centrifugal compressor can be installed for about $70 per horsepower and this results in a ratio of first costs of four for the gas engine reciprocating compressor in-

Figure 1. Typical capacity curves of gas transmission lines

Figure 2

stallation, to one for the electric centrifugal compressor installation. Another factor which favors the electric centrifugal installation is that it consumes no fuel and can deliver at destination practically the same volume of gas as introduced at the origin of the line, and further this gas not consumed enroute is worth the ultimate delivered sales value. This matter is important when one realizes that any given gas engine station will generally consume as much gas in a year for fuel as is its daily capacity. Thus in a long pipe line equipped with gas engines consisting of 20 stations, the annual consumption of fuel would be 20/365, which in the case of the "Big Inch" system capable of delivering 450 to 500 million cubic feet per day, would amount to a loss in annual revenue of almost $2,500,000. In making a comparative operating cost study, this loss in ultimate revenue would appear as a credit to the electric operation cost. Probably the most important factor however which influences the use of electric power in natural gas transmission, is that pipe lines never operate at 100 per cent capacity day after day throughout the year. As shown in Figure 1 of the discussion, when this decrease in capacity factor occurs, the energy required for pumping falls off rapidly, and the energy required expressed in per cent of maximum is equal to the capacity factor expressed as per cent of maximum design capacity raised to approximately the third power.

Since fuel costs represent only 15 per cent of the total operating costs of a gas engine station, any change in fuel usage due to lower capacity factors of the line, will not materially affect the total operating cost. On the other hand in the case of electric driven equipment, where the electric energy cost represents 80 per cent of the total operating costs, any change in electric energy use due to lower capacity factors of the line, will tend to affect the total operating expense a great deal.

The author has developed theoretically a great deal of information to show that the constant speed induction motor for the main pumps can be used satisfactorily when decreased capacities are desired. This is true for all situations of oil gravities and viscosities, and the variable speed motor is not considered essential for economic operation except for the occasional installation of the small suction booster pumps mentioned.

To illustrate the economy in energy consumption by a long oil pipe line operating at decreased capacities is shown by Figure 2 of the discussion. Each pump station contains 2 400 horsepower induction motors, each driving a centrifugal pump capable of delivering full capacity and one-half total line pressure. If one motor in each station is operated, the capacity obtainable is 70 per cent, and if every other station is shut down the capacity is about 60 per cent. Many other combinations are also possible, such as one motor operated in every other station for 40 per cent capacity, and so forth. From Figure 2 of the discussion, note that the energy usage when expressed in per cent of maximum varies approximately as the square of the capacity factor when expressed in per cent of maximum design capacity. For the seven year period from Figure 2, the average capacity factor was 80 per cent and the electric energy consumed was only 63 per cent of the amount which would have been required at 100 per cent capacity operation.

As explained previously for gas pumping, oil pipe lines never operate at 100 per cent capacity over a period of time, and the economic use of electric power at decreased capacities permits the electric station to readily compete with the Diesel engine driven station, which fact accounts for the widespread use of motors for the pipe lines handling oil or oil products.

The author under the heading Motor Construction covers the use of explosion-proof motors, and savings made by eliminating the fire wall between the pump room and motor room. The explosion proof motor costs more than the open-type motor and consequently many stations are constructed with ordinary induction motors by venting the air ducts to outdoor openings and thereby eliminating the fire wall.

The author has not mentioned his company's contribution to the pipe line industry, but the double rating horsepower motor is worthy of particular mention. It generally happens that pipe lines, particularly products lines, have use for a 50 per cent increase in power capacity after the original installation is made, because midway intermediate booster stations become necessary to keep up with the demand for oil products. This necessitates a 50 per cent increase of horsepower at the original station, and the 600/900 horsepower or 300/450 horsepower motor was developed. The increased output of the motor was obtainable by merely adding some fan blades to the rotor to increase the ventilation, thereby maintaining the same temperature on the motor coils when more work was required of the motor.

This discussion is not offered in any sense as being critical of the fine presentation made by the author of the many contribu-

tions the electric motor manufacturers have made to the pipe line industry. While this discussion may seem to stray somewhat from the original text of the paper, it was felt that the matters of relation between capacity factor and electric power usage should be presented, because they are the most important matters from an economic viewpoint, which govern the choice of motors over Diesel engines in this industry. Surely some of the readers would wonder why electric power would be used when consideration is given to the wide spread between electric energy costs and the cost of fuel to produce the equivalent energy.

Oil Production by Electric Power

W. G. TAYLOR
NONMEMBER AIEE

IT is well known in the oil industry that no two oil wells are alike. However, their operation in producing oil falls into certain definite patterns which simplify the design, selection, and use of mechanical and electric power equipment necessary to maintain the production throughout the useful life of each well. It is the purpose of this paper to cover the specific conditions affecting the application of electric power to the operation of producing oil wells, the selection of electric equipment suitable for this purpose and the layout of electric power distribution systems in the oil fields. The magnitude of the production branch of the petroleum industry in the United States is indicated by the statistics in Table I. This table also shows the extent to which electrification has progressed and the estimated potential electric power market of the future.

Ten Methods of Producing Oil

Although oil wells drilled in a new field may flow naturally for a few weeks, months or even years, due to underground gas or water pressure, this pressure will eventually be dissipated to a point where oil flow will cease. Some artificial method of producing the oil must then be adopted. In the older oil fields the underground reservoir pressure may already be largely exhausted, and new wells drilled in such fields require artificial production methods immediately. There are thousands of such wells drilled every year. Most of the methods used to produce oil by application of power are included in the following list. Electric drive is applicable to all of them.

1. *Beam pumping of individual wells.* About 90 per cent of pumped wells are producing by this method, which employs a power-driven pumping unit incorporating a walking-beam to actuate a deep-well reciprocating pump by means of sucker rods.

2. *Central-power pumping of wells in groups.* In this method, a central power-driven unit actuates pull rods extending to the wells to operate the deep-well pumps. This unit is usually called a power.

3. *Gas lift.* Natural gas, or sometimes air, delivered by power-driven compressors, blows the oil out of the well. The operation may be continuous or intermittent.

4. *Centrifugal bottom-hole pumping.* This is exclusively an electrical application, using a submersible motor-driven centrifugal pump unit lowered into the well. This method sometimes has been combined with gas lift, to pump oil part way up the hole and then blow it out the rest of the way.

5. *Hydraulic pumping.* The deep-well reciprocating pump is actuated by oil under pressure, which is delivered down the hole by a power-driven pump at the surface.

6. *Plunger lift.* A free-traveling plunger actuated by gas pressure lifts the oil by moving the entire length of the tubing from the foot-piece to the flow head at the surface. The gas is delivered from power-driven compressors.

7. *Pneumatic rod lift.* The rods connected to the deep-well pump are raised and lowered by an air-actuated piston in a cylinder at the surface. Power-driven air compressors supply the air.

8. *Casing rod pumping.* In this method, the reciprocating deep-well pump, fixed in the casing at the bottom of the well and actuated by sucker rods from a pumping unit at the surface, delivers the oil up through the casing without the use of tubing.

9. *Swabbing.* The oil is produced by a swab which is raised and lowered in the well casing by a power-driven hoist. This method is employed for production only temporarily or in special cases.

10. *Repressuring.* This is an indirect method of production by prolonging the natural flow of wells. Natural gas is forced into the oil-bearing formation by power-driven compressors, to maintain sufficient underground reservoir pressure for the wells to continue flowing.

Table II shows the approximate limitations of each of these methods of production from the standpoint of depth of well and amount of production, and the approximate range of horsepower requirements. The application of electric drive to methods 1 to 5, inclusive, will be discussed in this paper, since they are employed in many oil fields. The other methods, except number 10, are not extensively used and will not be considered further. Some additional comments will be given on repressuring.

Control of Production from Flowing Wells

By means of automatic electric control, the flow of each individual well in a group of flowing wells on a property can be accurately timed in accordance with proration or other requirements. The flowing period each day can be scheduled progressively, simultaneously, or with any desired overlapping. The lease tanks can be filled consecutively or in the order of their emptying. When all tanks are filled, the flow stops automatically until a tank is again available. When a day's production quota is met, the oil flow is stopped until the next day, when it is resumed automatically on the same schedule. Such operation is accomplished by a time switch on each well, controlling electrically operated and interlocked valves. A master timer starts and stops the daily program, and temporarily stops all scheduled operations if an emergency arises. All operations can be recorded automatically.

Beam Pumping

Beam pumping uses a single-acting reciprocating pump located in the well. In

Paper 48-150, recommended by the AIEE chemical, electrochemical and electrothermal committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted January 29, 1948; made available for printing April 12, 1948.

W. G. Taylor is with the chemical and petroleum division of the General Electric Company, Schenectady, N. Y.

For considerable data used in this paper, the writer is indebted to many engineers, particularly to W. H. Stueve, Oklahoma Gas and Electric Company, L. S. Peterman, Southern California Edison Company, and also to W. C. Bloomquist and J. N. Poore, General Electric Company.

Figure 1. Oil-well beam pump

its simplest form, Figure 1, it consists of a working barrel with a valved plunger. The working barrel is attached to the lower end of a string of tubing. The plunger is suspended from a string of sucker rods which is hung from the walking beam and extends down inside the tubing far enough to keep the plunger inside the working barrel. The motion of the walking beam provides the reciprocating motion for the pump plunger. On the down stroke the lower valve closes and the upper valve opens to pass oil. On the up stroke the lower valve opens to admit oil and the upper valve closes to enable the plunger to lift the column of oil in the tubing.

The walking beam is actuated by a pitman connected to a crank on a gear reduction unit. The latter is usually connected by a V-belt drive to the pumping motor (Figure 2).

The oil lifted through the tubing by the pump is discharged through the lead line shown in Figure 1.

Pumping speeds vary widely, but generally range from 15 to 20 strokes per minute. A pumping speed under 10 strokes per minute is usually called slow motion pumping. High speeds up to about 35 strokes per minute are used in some cases to obtain a profitable amount of oil when the well produces a high percentage of water.

Normal practice is to confine the work of the motor to pumping and to employ a portable hoist to pull the rods and tubing when it is necessary to make repairs, replace pump parts, or clean out the well.

Method of Estimating Beam-Pumping Horsepower Requirements

Formulas which follow can be used for estimating horsepower requirements if due regard is given to the fact that some indeterminate factors may affect materially the power required. If, for example, the volumetric efficiency of the pump differs much from that assumed, or if a well produces considerable gas or sand, the calculations are likely to be quite inaccurate for the current operating conditions. Judgment and experience must be depended on to supplement the calculations and to interpret them in terms of probable future conditions.

Barrels per day =

$$\frac{3.1416 \times R^2 \times L \times S \times (\text{hrs pumped daily}) \times 60 \times 0.75}{231 \times 42}$$

Where

R = radius of pump plunger in inches
L = length of stroke in inches
S = strokes per minute
60 = minutes per hour
0.75 = assumed volumetric efficiency of pump
231 = cubic inches per gallon
42 = gallons per barrel

Hydraulic horsepower =

$$\frac{(\text{barrels per day}) \times 42 \times 8.33 \times (\text{depth in feet})}{(\text{hours pumped daily}) \times 60 \times 33{,}000}$$

Where

42 = gallons per barrels
8.33 = pounds per gallon of water (can substitute weight of oil if known, but allowance must be made for probable water content)
60 = minutes per hour
33,000 = foot-pounds per minute per horsepower

Friction horsepower at polished rod =

$$\frac{(\text{weight of rods in pounds}) \times (\text{stroke in inches}) \times (\text{strokes per minute})}{1{,}600{,}000}$$

Where

1,600,000 = empirical factor determined from many tests

Motor horsepower rating =

$$\frac{(\text{hydraulic horsepower}) + (\text{friction horsepower at polished rod})}{0.93 \times 0.7}$$

Where

0.93 = assumed mechanical efficiency of pumping unit
0.7 = motor heating factor on pumping duty cycle

Figure 2. Typical oil-well beam pumping unit

In explanation of the motor heating factor of 0.7 in the last formula, it will be seen that the calculated hydraulic horsepower is based on average daily production and therefore is the average horsepower. The fluctuation of current on the pumping stroke is of such character that the heating effect or rms of the load, which determines the motor rating, is approximately (average horsepower)/0.7.

Types of Motors Used for Beam-Pumping and Some Application Factors Involved

The 3-phase squirrel-cage induction motor is almost universally used for beam-well pumping. This motor is available in three types, which for brevity will be designated by letters. They are the normal-torque or *NT* motor, the high-starting torque or *HT* motor, and the high-slip or *HS* motor which also has high starting torque. For this service only motors rated on a continuous basis should be used.

Some or all of the following factors are involved in the selection of the most suitable type of motor.

1. A rather high starting torque is required for a pumping unit. In cold weather the high viscosity of the grease or oil in the bearings and gear unit demands an especially high starting torque which may be out of proportion to the motor size. Therefore, small motors need a relatively higher starting torque in percentage of full load torque than do large motors. The actual foot-pounds starting torque required, over a range of motor sizes used on pumping units, will not vary nearly as widely as the motor sizes. Usually there is not much advance information as to how great the required starting torque will be. It is therefore customary to apply a motor with a high starting torque (approximately 250 per cent of full load torque), such as the *HT* or *HS*. when the rating is under 10 horsepower,

For motors of 10 horsepower and larger, it is reasonably safe to apply the normal starting-torque motor (approximately 150 per cent of full load torque), unless other reasons dictate the use of the *HT* or *HS*. On some specific applications it has been found advisable to use the *HT* or *HS* for 10, 15, or 20 horsepower sizes to insure sufficient starting torque. Such decisions must be based on local operating conditions. For example, *HT* or *HS* motors are often advisable for wells with paraffin troubles.

2. On the normal duty cycle of a beam-pumping unit, there are two power peaks on each pumping stroke, one when the rods and oil are lifted, and the other when the counterweight is lifted. When the electric power supply is generated in a small isolated power plant, these recurring peaks of a group of wells will periodically coincide, as illustrated in Figure 3, and result in unsatisfactory voltage regulation. Under these circumstances, and regardless of all other considerations, high-slip motors (having 8 to 13 per cent slip instead of a normal of approximately three per cent), should be used to reduce the current peaks (Figure 4). If the power is purchased, or if the isolated power plant is large, either *NT* or *HT* motors can be used, provided other conditions are favorable.

3. By slowing down as the peak load comes on, the high-slip motor allows energy stored in the rotating parts of the rig and motor to help carry the peak. Some operators desire this type of motor for the cushioning on the power system resulting from this speed variation. However, cushioning of mechanical shocks in this manner will be obtained only if the average strokes per minute are allowed to drop correspondingly, and even then the effect will be small. As this would probably decrease the production from the well and possibly give a speed out of resonance with the sucker rods, normal practice is to use different V-belt drive ratios for high-slip and normal-slip motors, so as to obtain the same pumping speed in either case. Under these circumstances there is no material difference in the mechanical shock loads and the only cushioning effect is that obtained in the electric input to the motor.

4. High pumping speeds, of approximately 30 to 35 strokes per minute, are used in many cases, such as wells producing a very high percentage of water. Such speeds result in high motor-input peaks even when the pumping units are properly counterbalanced. High-slip motors give the best results in such cases, as they reduce the current peaks and minimize the motor heating.

Although the efficiency of the high-slip motor is lower than that of the normal-slip motor, this does not necessarily mean that the former will have a higher power consumption. The reduction in current peaks effected by high slip reduces the power losses in proportion to the square of the current, which may more than offset the effect of the lower motor efficiency. Even this is not necessarily the result in all cases, as it depends on the conditions at each well. The net result may be an increase or decrease in power input, but too small to be a factor in the selection of the size of motor.

Guide to Motor Selection for Beam Pumping

In line with the foregoing considerations, the following guide to motor selection is offered to cover the most important factors. There are many other conditions in oil-well-pumping service which can influence motor selection, especially in borderline cases. No attempt will be made to cover these, because they are usually obvious to engineers and specialists who give the applications careful consideration.

1. The normal-slip normal-starting-torque (*NT*) motor is usually applied when:

a. The motor size is 10 horsepower or more, and power is supplied from a large generating plant or from the power system of an electric utility and where the wells are properly counterbalanced and paraffin not excessive.

b. The evidence obtained from tests, or from comparison with other wells, shows conclusively that 150 per cent starting torque will be sufficient.

2. The normal-slip high-starting-torque (*HT*) motor is usually applied when:

a. The required motor is less than 10 horsepower, unless it is definitely known that an *NT* motor will be satisfactory.

b. Existing well conditions are not thoroughly known.

c. There is conclusive evidence that very high starting torque (up to 250 per cent of full-load torque) is required.

3. The high-slip high-starting-torque (*HS*) motor is usually applied when:

a. Power is supplied from a small isolated generating plant. This recommendation holds true regardless of all other considerations.

b. The user desires the additional cushioning effect which the high-slip motor provides, as compared with a normal-slip motor.

c. Under any conditions, it is advisable to reduce the momentary current peaks.

d. An unusually high pumping speed is required, resulting in very high peaks, for example, when the water/oil ratio is high.

Both high-slip and medium-slip motors are available. As the slip permits the stored energy in the rig to carry part of the peak load, and as this stored energy is small under any circumstances, the high-slip motor should be used so as to utilize the available stored energy as fully as possible.

Double- and Triple-Rated Motors for Beam Wells

The triple-rated single-speed squirrel-cage induction motor has three horsepower ratings in the ratio of 10-7-4, obtained by changes in stator connections, and all at the same speed; the double-rated motor is the same with connections for the intermediate rating omitted. The main advantage of the lower ratings is to improve the power factor on the lighter loads. A slightly better efficiency may also be gained. Where the power requirements of the various wells on a lease differ considerably, such a motor, applied in the same size to all the wells, will give maximum flexibility in the use of motors on light or heavy wells, while keeping the stock of spare motors and renewal parts down to a minimum.

In the initial stages of pumping after a

Table I. United States Oil-well Pumping Statistics at the End of 1946

Total number of producing wells	424,286
Number of free-flowing wells	48,387
Number of pumped wells	375,899
Percentage of wells pumped electrically (January 1946), approximately	21
Installed electric motor horsepower for oil production (January 1946)	772,000
Annual electric power consumption, kilowatt-hours	1,515,000,000
Oil production in 1946, barrels	1,731,889,000
Oil produced electrically in 1946, barrels	363,700,000
Average electric power consumption, kilowatt-hours per barrel	4.2
Estimated potential electric power market for wells pumped by other than electric drive, kilowatt-hours per year	5,746,000,000
Number of wells put on the pump in 1946	14,441
Estimated potential electric power market for wells put on the pump annually, kilowatt-hours per year	277,267,000

Table II. Oil Production Methods

Producing Method	Depth of Producing Well in Feet Minimum	Depth of Producing Well in Feet Maximum	Fluid Required to be Pumped from Each Well, Barrels per Day Minimum	Fluid Required to be Pumped from Each Well, Barrels per Day Maximum	Horsepower of Prime Mover Required per Well Minimum	Horsepower of Prime Mover Required per Well Maximum

Figure 3. Load characteristic of a group of beam-pumped wells

Figure 5. Power consumption of beam-pumped wells listed in Table III

well has ceased flowing, the lowest rating may be used, because the remaining reservoir pressure will still help to lift the oil. As this pressure declines, the intermediate rating and eventually the highest rating will be required. Then in time as production declines, the lower ratings may be used again. These changes of rating will also be advantageous to match changes in allowable production under proration rules. The highest rating may be used also for driving a friction-clutch rod and tubing hoist.

Recent trend has been away from this type of motor in favor of several sizes of single-rated motors, the practice being to change the motor size on a well to suit changing conditions. Generally a field does not require pumping to be started all at one time, but it begins at one edge and progresses across the field. The smaller sizes of motors are used at the front line, and larger motors progressively to the rear.

Motor Enclosure for Beam Wells

Well-pumping motors are usually installed outdoors. They are available with dripproof, splashproof, totally enclosed fan-cooled, and explosion-proof frame constructions. The present trend is toward the use of dripproof motors where splashproof have been used extensively in the past. Under severe weather conditions, the totally enclosed fan-cooled motor will give long service with less maintenance than either the dripproof or the splashproof motor. In a few places where heavy snow and sleet conditions prevail, dripproof motors enclosed in ventilated "doghouses" or sheds have been used. Explosion-proof motors are not required normally because the well is capped when the motor is operating, and the motor is shut down when the well is open.

Control for Beam-Pumping Motors

Control equipment is assembled in a pole-mounted, ventilated, outdoor case. It normally includes a fused line switch, a motor-starting magnetic switch, a control switch, undervoltage and temperature overload protection, and, when required, an automatic time switch and a lightning protector.

Time-cycle pumping is used where production is prorated, or where stripper wells are pumped only a few hours a day. The time switch starts and stops the motor automatically at preadjusted times each day, and may be arranged to stop the pump one or more days a week if desired. Exact production schedules are thus met on time without attention from the pumper. Stripper well production may be increased by proper timing. For example, in one case a well pumped by manual control once a day required 12 hours to fill to its maximum head, but filled to 70 per cent of this head in six hours. By means of time-switch electric-motor control, it was pumped twice a day at 6-hour intervals, and produced 140 per cent (2×70 per cent) of the oil previously produced, a gain of 40 per cent.

Power Consumption for Beam Pumping

As oil wells differ in their characteristics, and the operating conditions of each change from time to time, estimates of electric power consumption are not only difficult to make but are likely to be inaccurate. When wells cease flowing and go on the pump, the power increases progressively as the reservoir pressure declines, and then eventually decreases as production declines. The point in the productive cycle at which electric drive is applied will govern, to a large extent, the power consumption to be anticipated.

Figure 4. Effect of a high-slip motor in reducing current peaks on a beam-pumped well

Although the status of the production cycle was not available for the 207 wells listed in Table III, a considerable range of depth is covered, which makes it possible to plot the power consumption curve shown in Figure 5. This is a fairly representative curve, although for small producers increasingly higher average kilowatt-hours per barrel can be expected with increase in depth.

Effect of Counterbalancing Beam Wells

A walking-beam pumping unit is counterbalanced by weights mounted on the end of the beam or on the crank. By adjustment they offset the weight of the rods in the well plus about half of the weight of the oil lifted on each stroke.

The best possible counterbalancing makes the two power peaks equal (Figure 6). This can be checked readily by a portable ammeter.

Proper counterbalancing not only reduces the torque required to rotate the crank but also minimizes the power consumption because of the reduction in losses.

Beam-well Cost Considerations

It is practically impossible to prepare a general cost comparison between electric drive and other forms of power which will be of much value for consideration of specific applications. This is due to wide variation in operating costs as well as conditions. Furthermore, oil company records of performance are very often so incomplete, or pertinent costs are so frequently charged to and buried in general accounts, that it is difficult to determine facts essential for a comparison. Con-

sideration of costs will therefore be confined to some available data and a few comments.

A chart of relative installation costs of four types of beam-pumping equipment is shown in Figure 7. As the costs were determined in 1938, they will be far from correct now, but the comparison is of interest. The data were derived from reliable contractors and equipment manufacturers, and applies to mid-continent wells producing 300 to 400 barrels per day from a depth of approximately 4,000 feet and equipped with 40-horsepower engines or 25-horsepower motors. Another comparison, shown in Figure 8, is based on costs (1940–1941) in Illinois oil fields, covering electric motors and multicylinder gas engines.

In figuring operating expenses, some operators are inclined not to give due consideration to fixed charges, which are of course important factors. Before the war, interest was usually figured at six or seven per cent, but varied with the locality and the apparent risk involved. Depreciation of ten per cent per year is conservative. Taxes and insurance average about three per cent per year.

Operating costs include power, labor and maintenance. Gas used should be charged at its marketable value, if any. Labor cost will depend on the number of wells which can be attended by each pumper. Maintenance includes costs of repairs, renewal parts, reconditioning, and lubrication. In making comparisons between various forms of power, consideration should be given also to loss of production due to shut-downs and to the relative amount of rod breakage experienced. Shut-downs may not be important on part-time producers, but rod breakage can be so on any beam well. For example, on a West Virginia property, installation of electric drive resulted in the practical elimination of rod breakage on wells where breakages had previously averaged one a year per well. Under similar circumstances in Venezuela, rod failures which had averaged between three and four a year per well were reduced over 80 per cent after electrification.

Central-Power Pumping

In central-power pumping, the power from a single motor is transmitted mechanically to a group of wells through a pull-rod system. The motor drives a vertical shaft eccentric, and pull-rods are hooked to the eccentric strap. They extend horizontally to the several wells, where they actuate pumping jacks, similar to bell cranks. To these are attached the sucker rods in the wells. The motor drives the rig through either a bevel-gear drive (Figure 9) or a large vertical-shaft band-wheel with belt drive. The direction of pull of each well on the eccentric is so laid out, by mechanical means, that the wells counterbalance each other. When the wells are pumped intermittently, they are hooked to the "power" on a staggered schedule and the "power" runs continuously. Experience is the only practical rule for estimating the power requirements. Records of a large number of very shallow wells, 1,000 feet or less, show an average of 1.5 horsepower per well, and a minimum of less than 1 horsepower. Power consumption of several groups of wells is shown in Table IV.

A standard squirrel-cage or slip-ring induction motor with simple starting and protective equipment usually meets all requirements for central-power pumping.

Gas Lift

The gas-lift method of oil production is used occasionally. It employs compressed natural gas to blow the oil out of the well. Air may be used sometimes when there is insufficient gas. By the simple method illustrated in Figure 10, the gas is forced down through a pipe suspended in the hole, and blows the oil up through the tubing.

A group of 75- or 100-horsepower compressors, according to the oil company's individual requirements, is the usual type of installation. Standard squirrel-cage induction motors are used to drive the compressors.

Because all of the heat of compression of the gas is lost, this is a costly method of producing oil, but it has the advantage of being able to handle large volumes of fluid.

Centrifugal Bottom-Hole Pumping

A well with heavy potential production in excess of the capacity of deep-well reciprocating pumps can be pumped with a submersible centrifugal pumping unit. Such a unit consists of a cylindrical, multistage, centrifugal pump driven by a high-speed squirrel-cage induction motor of the same diameter, and directly coupled to the pump with an intervening sealing unit. The complete unit is suspended in the well by tubing, and receives electric power through a cable clipped to the tubing. The required motor capacity depends on the number of stages in the pump. Sizes available range from 52.5 horsepower in $4^1/_8$-inch outside diameter and 97.5 horsepower in $5^3/_4$-inch outside diameter up to 135 horsepower in $5^3/_{16}$-inch outside diameter, providing for all well depths down to 10,000 feet.

Power consumption is approximately 1/3 kilowatt hour per barrel of fluid produced per 1,000 feet lifted. The efficiency of the pumping unit is approximately 30 to 45 per cent.

Supplementary equipment includes a cable reel, a starting panel, and either a special transformer or a special a-c generator. About 900 volts must be available above ground to allow for the voltage drop in the cable leading to the motor.

Hydraulic Pumping

This method employs a double-acting deep-well reciprocating pump actuated by

Figure 6. Power input to two beam-pumped wells, illustrating the effect of counterbalancing

a direct-connected power piston which is operated by oil under pressure. The pump is suspended in the well on tubing and submersed sufficiently to insure filling of the pump cylinder on each stroke. The oil to actuate the power piston is supplied by a triplex pump located above ground and driven by a squirrel-cage induction motor. This oil is pumped down to the power cylinder through a small string of tubing suspended inside the larger tubing, and is then discharged into the stream of oil produced from the well, which is pushed to the surface in the annular space between the two strings of tubing.

Equipment is available for pumping wells from 1,500 down to 10,000 feet on either single or multiple well hookups.

Power consumption is approximately 1.4 kilowatt hour per barrel of fluid for a pumping depth of approximately 6,400 feet, or 0.22 kilowatt hour per barrel per 1,000 feet of lift. The horsepower required depends on the pump size.

Secondary Recovery by Water-flooding

Water-flooding operations involve the injection of water at high pressure into the oil-bearing formation to force the oil to key wells, which are usually pumped by beam-pumping units or central "powers." The water supply is usually pumped from deep wells or lifted by compressed air. It is then chemically treated and filtered, pumped through a pipe line to the oil field, and forced underground by high-pressure injection pumps. The application of electric drives to these operations follows standard practice for the type of apparatus involved.

Control equipment for water-flooding systems must be completely reliable. Shutdowns must be avoided if possible, because they mean loss of production and possible detrimental effect on the progress of water flooding. Simple, automatic operation shortens many unavoidable shutdown periods, lowers the labor cost per barrel, saves time and reduces maintenance costs. The judicious employment of automatic motor starters, electric float switches, pressure switches and time switches will accomplish these purposes readily.

A few points deserve special mention. If an electric power failure stops a deep-well centrifugal water pump, the water standing in the vertical discharge pipe will rotate the pump backwards unless there is a ratchet head or other nonreversing device. If power is restored during reverse rotation, the pump shaft may be twisted off, but this can be obviated by a time relay which will keep the motor from starting until the pump has had time to stop running backward.

Injection pumps must be protected against loss of suction pressure. A pressure switch, operating on pump-suction pressure, is adjusted to trip the motor starter when the pressure goes below the permissible minimum. This prevents also the pipe line from filling with air.

Excessive voltage drop resulting from simultaneous automatic restarting of a large number of motors can be avoided by restarting in successive groups controlled by definite-time-delay relays. This avoids also the danger of collapsing the suction manifold of a group of pumps before the water has time to get to the pumps.

Repressuring

To maintain the underground reservoir pressure and thus prolong or increase well flow, natural gas stripped of condensates is in many fields returned under pressure to the oil producing formation. Usually steam is required in processing the gas, and can be used first to generate electric power. Before a specific plant is designed, a careful economic comparison should be made between the steam-electric and the gas-engine system, because the market value of excess gas is increasing, steam-

electric maintenance costs are comparatively low, and the demand for electrified auxiliaries is increasing.

A typical steam-electric plant uses steam-turbine generators, motor drives for compressors and pumps, cooling tower motors and control, auxiliary motors, switchgear, unit substations, auxiliary power transformers, and lighting equipment. Such a system is illustrated diagrammatically in Figure 11.

Electric Power Distribution for Well Pumping

Approximately two thirds of the cost of electrification of an oil field is for the power-distribution system; the remaining one third is for the motors and control. It is quite important therefore that the distribution system be laid out carefully, with due consideration of cost.

The factors which affect the layout and type of the distribution system are as follows: permissible voltage drop, cost of system, number and sizes of motors, well spacing, configuration of the field, pole spacing, size and type of line wire, power factor, and service reliability.

A system consists usually of 2,400-, 4,160-, or 13,800-volt primary feeders extending into the field, with transformers at strategic locations stepping down to 480 volts for supplying a group of wells. The load is much more widely distributed than in ordinary industrial plants, and each well is usually relatively small in horsepower requirements. The load distribution makes it necessary to run secondary feeders for as great a distance as voltage conditions will permit.

Voltage Drop

This is the main consideration in the layout. Motor current is commonly supplied at 440 volts over long feeders, with a low operating power factor, and voltage drop determines to a large extent the cost of the system. Good practice requires that the operating voltage, after the motors are started, should be not less than 95 per cent, nor more than 110 per cent, of the motor nameplate voltage. Although motors will operate at less than 95 per cent, and manufacturers guarantee noninjurious temperatures with operation at 90 per cent of motor nameplate voltage, a minimum operating voltage of 95 per cent allows some margin for the voltage drop occasioned by starting a motor. These limits of 95 and 110 per cent are permissible in oil field practice, though they have a slightly wider spread than generally recommended by the AIEE subcommittee on industrial voltage requirements.

The voltage at the motor during starting should be at least 80 per cent and preferably 85 per cent of the motor nameplate voltage. Flicker of field lights at the time a motor is started is not important.

In a well-planned system the voltage drops will ordinarily be from one to three per cent in the primary line, two to four per cent in the transformers, and $7^1/_2$ to $12^1/_2$ per cent in the secondary line. The total drop at the most remote well should be not more than 15 per cent of the no-load voltage, which will give approximately 95 per cent of motor nameplate voltage at the motor terminals when using a transformer tap to give 5 per cent above rated transformer voltage. If capacitors are used, the drop becomes approximately 10 to $12^1/_2$ instead of 15 per cent. Obviously secondary lines should be as short as possible. For this reason it is preferable to use the load-center principle of power distribution, in which power at primary voltage is brought directly to the load area before it is stepped down to distribution voltage.

If utility power is used, the primary voltage will be fixed by the utility prac-

Figure 9. Motor-driven geared pumping "power"

Figure 10. A simple form of gas lift

Figure 11. Steam-electric system for repressuring with natural gas

Figure 12. System thermal capacity released by improving load power factor

For example, if the power factor of a circuit is improved from 65 to 95 per cent, the system can carry 35 per cent more load having 65 per cent power factor without exceeding the original kilovolt-amperes, and capacitors are more economical than additional system facilities for all S/C values above 1.55

tice, but if it can be selected, 4,160 volts results in very much less drop than 2,400 volts, at almost the same cost, and allows for future expansion. Higher primary voltage are seldom necessary and is not as economical.

Compensation for voltage drop may be made by the use of transformer taps, or by capacitors, or both.

Distribution Transformer Banks and System Protection

Single-phase transformer units are preferable. Generally transformer banks up to 45 kva and sometimes up to 75 kva are pole-mounted on cross arms. Above these sizes a double-pole and platform arrangement is commonly used. The transformers are of standard design, readily obtainable, easily handled, require a minimum of spare parts, and can still supply power at reduced capacity in the event of outage of one transformer of a delta-delta-connected bank. The delta-delta connection is preferable, not only for this reason, but because standard 2-coil overload protection of motors can be used. A Y-delta or delta-Y connection requires 3-coil overload protection for each motor to avoid burnouts in case a primary fuse or line is open and the bank has an ungrounded neutral. In such a case double current will occur in one secondary conductor, and 2-coil overload relays will not then provide full protection.

Lightning arresters should be included at each substation for maximum protection. The 440-volt systems are invariably ungrounded, so secondary arresters should be selected for ungrounded service.

Fused cut-outs are economical and are employed almost universally to protect transformer-bank sizes normally used in oil-field distribution service.

If oil company practice permits the bonding of electric connections to the well casing, it will provide a suitable ground for the pumping-unit frame, motor-starter case and lightning arresters. The usual alternative is to use ground rods.

Capacitors

In a 440-volt system it is expensive to reduce the voltage drop by increasing the conductor size. Capacitors are the answer to that problem, by improving the normally low-power factor of well-pumping loads, which is approximately 60 to 65 per cent. The saving in system losses by the use of capacitors is often economically attractive, as the losses are inversely proportional to the square of the power factor. In oil-field distribution systems, with relatively long secondary runs, it is not at all unusual for capacitors to pay for themselves through reduction in system losses alone. Furthermore, they release substation and line capacity for additional load (Figure 12), or permit the use of smaller transformers and conductors, and will reduce the cost of utility power if the rate contract includes a power-factor penalty clause.

Capacitors can be connected either at the motor terminals or on the feeder lines. The advantages and disadvantages of both methods of connection should be weighed to determine the choice, which depends mainly on the ratio of the number of wells in operation to the total number of wells pumped. If all are pumped simultaneously, capacitors at individual motors are preferable, but it is uneconomical to use the outdoor type for motors under 10 horsepower. If only part of the motors are in operation at any time, the group-capacitor method should be considered because of the lower investment.

Table V

900 to 1,200 Rpm Motors

Type of Motor	Starting Power Factor
Normal starting torque motor	30 to 50 per cent
High starting torque motor	35 to 60 per cent
	Motor Inrush (Times full-load current)
Normal starting torque motor	5.0 to 6.5 (Usually 6.0)
High starting torque motor	4.5 to 6.0 (Usually 5.0)

Type of Line Conductor

In sour gas areas, steel-reinforced aluminum conductors are generally used instead of copper because aluminum is noncorroding. The spans between poles

LOAD MULTIPLIERS FOR DIFFERENT RECEIVER VOLTAGES

Receiver voltage...	404	408	412	416	420	424	428	432	436	440	444	448	452	456	460	464	468	472	476	480
Kw. multiplier.....	1.186	1.163	1.141	1.119	1.097	1.077	1.057	1.037	1.018	1.000	0.983	0.965	0.949	0.931	0.915	0.899	0.884	0.869	0.855	0.840

for 440-volt line construction can be from 300 to 500 feet with aluminum, compared with 150 to 350 feet with copper. Thus, the pole cost for aluminum lines is roughly half that for copper lines. Since pole cost is an appreciable part of the total cost, alumimum conductors represent a large saving. For equivalent conductor size, the voltage drop and wire costs are about equal. Greater care is required in making satisfactory splices and terminations with aluminum.

System Layouts

As complete information for making a layout of an oil-field distribution system has been published,[1] only an outline of the method will follow.

Calculation of the many voltage drops in a system is simplified by using the unit-load–unit-length (*UL–UL*) principle. The motor loads on a specific oil property are in most cases close enough to permit each to be termed a unit load. If not, the property can be divided into areas with about the same unit loads. Wells on an oil property are usually spaced uniformly, and the distance between two adjoining wells can be used as a unit length. The voltage drop is determined for this selected load and conductor length, and this value (*UL–UL*) is used as a base for other combinations of loads and distances. For example, the voltage drop for 2 *UL–UL* may be for one-unit load and two-unit lengths or for two-unit loads and one-unit length.

Figure 13. Voltage-drop chart for 440 volts

The kilowatt input to a motor, or the unit load, corresponds to the average load on the motor, which for a fully loaded motor for pumping-unit service is 60 to 70 per cent of the motor horsepower rating. The unit load may be expressed as follows:

$$\text{Kilowatt input} = \frac{(\text{horsepower rating}) \times 0.746 \times 0.65}{(\text{motor efficiency})}$$

in which 0.65 is the assumed loading factor.

The next step is to determine the power factor of the unit load from published charts[1] applying to the type of motor used, with or without capacitors at the motor, as the case may be. With this data the *UL–UL* drop is read from published voltage-drop charts,[1] such as the one shown in Figure 13 for 440 volts. If the load is small, the drop may be read for a larger load and reduced in direct proportion to the loads. The total secondary drop is obtained by addition of the drops for the various *UL–ULs*.

A simple example will serve to illustrate the use of the *UL–UL* principle. Con-

sider a single secondary feeder, extending from the transformer bank halfway between two lines of wells, two on each side, thus feeding four wells which are spaced 660 feet apart and are pumped simultaneously. Assume a 10-horsepower 1,200-rpm 440-volt motor, high-starting-torque type, at each well, each fully loaded. The unit load, determined from the foregoing formula, is 5.4 kw. The unit length is the well spacing, namely 660 feet. The load power factor, determined from published curves,[1] is 70 per cent, expressed as 0.7.

The voltage drop for a unit load of 5.4 kw at 0.7 power factor and one unit length of 660 feet may be read directly from the 440-volt chart (Figure 13) for the size and type of line conductor under consideration, say Number 4 ACSR (aluminum cable steel reinforced) but not with any degree of accuracy for such a small load. A higher load, such as 40 kw, may be selected, for which the voltage drop is 7.65 per cent. The drop for one unit load of 5.4 kw is

$$\frac{5.4}{40} \times 7.65 = 1.03 \text{ per cent}$$

The voltage drop for 1 *UL–UL* is therefore, 1.03 per cent.

From the transformer bank to the junction of the branch circuits feeding the first pair of wells there are 4-unit loads and 1-unit length (4 *UL–UL*) and from the junction to each motor there is 1-unit load and 1/2-unit length (0.5 *UL–UL*). The total secondary drop to each of the first pair of wells is therefore for 4.5 *UL–UL*, which is 4.5 × 1.03 or 4.6 per cent. From the junction for the first pair of wells to that for the second pair there are 2-unit loads and 1-unit length (2 *UL–UL*), and from the second junction to each well there is 0.5 *UL–UL*, making a total of 2.5 *UL–UL*. To these are added the 4 *UL–UL* from the transformers to the first junction, making a total of 6.5 *UL–UL*, for which the drop is 6.7 per cent from the transformers to the second pair of wells.

The primary drop can be calculated in the same manner, using a voltage-drop chart for the primary voltage involved. Transformer voltage drops are covered by published tables.[1] The total voltage drop in the system is the sum of the drops in the primary circuit, the transformers, and the secondary circuit.

The voltage drop during the starting of a motor should be checked for the final distribution layout to make sure that sufficient voltage is available at remote well locations to start the motor. The drop in the primary lines can usually be neglected. For the transformer bank, it can be read directly from a table,[1] and for the secondary lines it can be read from the chart in Figure 13. The data in Table V are representative for motor-starting conditions.

For estimating purposes the full-load motor kva is usually taken as 1 kva per horsepower. Considering, for example, a 15-horsepower high-starting torque motor, the starting kva = 15 (horsepower) × 5.0 (inrush) × 1.0 (kva/horsepower) = 75.0. For a starting power factor of 40 per cent, the starting kw = $\frac{40 \times 75}{100}$ = 30 kw. The secondary voltage drop for this starting load is read directly from the chart in Figure 13 for a power factor of 40 per cent. When capacitors are used, this voltage drop will be 90 to 95 per cent of the drop without capacitors.

Estimating Installed Cost of Distribution System

Data for this purpose have been collected and are available.[1] These data permits quick cost comparisons of various alternative layouts and are useful in arriving at the most economical layout. The estimated total installed cost of the distribution system is based on the following component parts:

1. Pole types.
2. Conductors, including stringing and sagging.
3. Transformer substations.
4. Capacitor equipment, if used.
5. Add ten per cent to above total for such miscellaneous items as surveying, trucking, and other incidental costs.

For a final reckoning of the construction costs, the services of a reliable oilfield contractor should be enlisted. It is well to keep in mind that the major economies in electrification of an oil property can be effected in the power distribution system.

Discussion

E. H. Lamberger (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Taylor is to be complimented for presenting a paper which covers so many of the important items which must be considered when planning the electrification of an oil field.

The author's method of estimating beam-pumping horsepower requirements necessarily includes a formula for calculating the daily fluid production. One essential factor of the formula is length of stroke. Production is basically a function of the pump plunger stroke. This is usually not the same as the polished rod stroke due to the elastic characteristics of the rod string. The elastic characteristics involve such factors as length of rod string, speed of pumping, polished rod, stroke length, fluid load, and damping factor. The pump plunger stroke may be either greater or less than that of the polished rod. Obviously, it is desirable to use the actual pump plunger stroke, to assure highest possible accuracy of the calculated horsepower requirement.

We believe it would be well to call attention to a formula for calculating actual plunger stroke. This formula was given in an American Petroleum Institute paper in 1941.[1] The complete derivation of the formula is given in a paper[2] at the applied mechanics division meeting of the American Society of Mechanical Engineers in Cambridge, Mass., in 1942.

Basing the motor horsepower on hydraulic horsepower plus a value for subsurface losses is sound, and we believe should give more accurate results, for wells of modern straightness, than the commonly used method of assuming the friction losses to be some multiple of the hydraulic horsepower at the pump. This assumption results when the motor horsepower is derived by simply dividing the hydraulic horsepower at the pump by a factor representing some commonly assumed ratio of hydraulic to motor horsepower.

The formula given for subsurface friction horsepower results in a straight line relation between friction horsepower and speed of pumping. Since subsurface friction is a function of mechanical friction between rods and tubing, and two components of fluid friction, that of the rod string and fluid and that of the fluid and tubing, a curved relation, concave upward, is indicated. Such a curved relation is indicated by the formula for fluid friction because it includes a factor of velocity squared in the numerator. The curved relation has also been shown by careful tests. These tests, with a 3,500 foot string of 3/4-inch rods, showed 0.5 horsepower per 1,000 feet of string, at 1,000 inches per minute rod velocity, 1.2 horsepower at 1,750 inches per minute, and 2.5 horsepower at 2,500 inches per minute.

The author mentions 8 to 13 per cent slip, high-slip high-torque oil well pumping motors. We believe it should be stated that high-slip motors with a slip of 5 to 8 per cent have been and are being commonly and successfully used.

W. H. Stueve (Oklahoma Gas and Electric Company, Oklahoma City, Okla.): This paper describes practically all the known methods of producing oil and the part that can be played by the electric motor application to the machinery required. Until recent years, the oil producing phase of the industry has been slow to adopt changes from conventional practices and sought maximum daily results regardless of the economics of its producing methods. The recent advent of the professional petroleum engineer into this business has changed the oil executives viewpoint to such an extent that, today, primary recovery methods are selected based on the mechanical and/or electrical efficiency of the equipment, with further consideration being given to correlating such primary methods with expected future secondary methods of recovery. This is important, for formerly only about 30 per cent of the oil in place in a given pool could be recovered with primary methods; whereas, an additional 20 to 30 per cent of all the original oil in place in a pool can be recovered now with secondary methods, such as gas repressuring or water flooding.

For this reason, it might be well if the efficiencies of the ten methods of production, shown in author's Table II, be given more consideration in the final analysis to determine the selection of the proper economic type of equipment. Figure 1 of the discussion is a study of almost 2,000 producing wells equipped with all types of pumps, motors (normal and high slip) covering the five general methods spoken of by the author, as adapting themselves to electric power. The "Max" line represents 28.5 per cent efficiency, "Mean" 36.3 per cent, and "Min" 48.7 per cent, all production being reduced to 1.0 specific gravity, and reading in kilowatt-hours per barrel versus feet pumping depth. Figure 1 of the discussion clearly points out the type of equipment which is the most efficient at the various pumping depths. Beam pumps and central powers, in some cases, are most efficient for wells approximately 3,000 feet deep; the submerged-centrifugal pump is most efficient for wells approximately 4,000 feet deep; and the hydraulic powered pump for wells 6,500 feet deep. It should be mentioned, however, that the most efficient method can not always be used, as shown in the limitations of capacity in Table II. Thus, we find that hydraulic powered pump will only produce up to 300 barrels per day at 6,500 feet depth; whereas, the centrifugal bottom hole pump, while not as efficient, yet it is the only pumping unit that can be used for volumes up to 1000 barrels per day from that same depth. This accounts for the 178 installations of the centrifugal bottom hole pumps as against only eight of the hydraulic powered pumps on Figure 1 of the discussion.

From the author's Table II of producing methods, no electrical records are available for the other methods, but, in general, it may be said that gas lift is only 10 per cent efficient and very expensive due to the great number of gas compressors required; further, governmental conservation commissions frown on this method since it takes production from surrounding leases whose owners may not ordinarily have the capital to make the more expensive installations. These same reasons apply to *4A*, the combination of *4* and *3*. In general, *4A* was used only to secure potentials of wells, and operated only in this manner for short periods of four to eight hours, so the method can not be construed as a permanent method. Note, however, that gas lifting in any form will produce large amounts of fluid. Pneumatic rod lift requires gas compressors and is only eight to ten per cent efficient, and is used only by producers already having on hand the necessary compressor equipment and having no other use for it at the time being.

The swabbing method is used only temporarily, perhaps during the first 10-to-20 days of the discovery of the well, while awaiting the permanent equipment. Note that the water flooding method from Table II for two groups of wells, is about 24 per cent efficient, 800 and 52 wells at approximately 600 feet depth.

The central powers method is efficient enough to meet most conditions, 30 to 40 per cent, except for limitations of depth being about 2,600 feet, and also relative small volumes of the order of 25 to 50 barrels of fluid per day. See author's Table IV, where average is 48.5 barrels per day from 96 wells studied.

It is true that about 90 per cent of all wells being pumped today are with beam pumps with individual power units (engines or motors) but the problem of rod breakage, and consequent loss of production while repairs are being made, has never been successfully solved. It is unfortunate that more electrical data are not available from the operation of the two types of submerged pumps, the centrifugal and hydraulic, from relative shallow depths below 4,000 feet, for it is felt that their use would prove more satisfactory and gradually solve the operator's problem of rod breakage by displacing the beam pump to a large degree.

The centrifugal unit now, however, is being made in small sizes of 5, 10, and 20 horsepower, especially for use in shallow wells, or wells of low volume. The hydraulic unit is now being promoted for shallow wells also, since the triplex pump supplying the power fluid is being centrally located between a group of wells, and the power fluid is distributed to individual wells in much the same manner as would be electric power.

Since 90 per cent of the oil wells are being pumped by the "beam pumps" method, the author had devoted a considerable portion of his paper to formulae for determination of horsepower required, and also to the selection of the type of motor to install for various conditions of wells. As a short cut suggestion to determine the motor size for a given condition, the average efficiency line from Figure 1 of the discussion can be used since it is plotted principally from points from the author's Table III. Thus, if the well is to produce 200 barrels of oil and water per day, from a depth of 4,400 feet then it will require two kilowatt hours per barrel of 1.0 specific gravity fluid or 400 kilowatt-hours in 24 hours. The average

Figure 1. Electric power required to pump oil wells

Figure 2 (right). Comparison down time for gas engines and electric pumping

electric load will be 16.6 kw input, or average 20 brake horsepower, requiring a 30 horsepower motor by applying the author's factor of 0.7 to compensate for peak loads during each stroke.

The author's Figure 3 clearly shows the effect of using normal slip (3 per cent) motors, in that peaks of 50 per cent greater than the average load can be encountered with only 12 wells in operation. In this case, the chart was moving at the rate of 12 inches per minute, and the change from 69 to 148 kw occurred in one second of time, which rapid change would impose a severe shock on any small generating equipment supplying the power. If high slip (10 per cent) motors had been installed on the 12 wells, the rapid load change would be reduced considerably and offer the small generating plant a better opportunity to carry the load. This reduction in peak loads achieved by high-slip motors for individual pumping units is best shown by the author's Figure 4.

When large groups of wells are considered, the effect of using high-slip motors is more pronounced, as shown in the Table I of the discussion.

A study of Table I of the discussion reveals that a more even power flow usually will be obtained from groups of wells equipped with high-slip (10 to 12 per cent) motors. While the normal-slip motor may have a lower first cost, yet the greatest cost of the high-slip motor may be compensated for to some degree in less rod breakage and, therefore, prove more economical in the long run. Also, note that the power factor of the normal-slip motors is considerably improved as the speed of the motor is increased. This is important to the oil producer since the higher speed motor generally is cheaper in cost and savings can be effected in transformer capacities and distribution system wire sizes. The data from this Table I bear out the author's opinion that more consideration should be given to using higher slip motors wherever possible.

The author's discussion of determination of wire sizes, distribution voltages, and the use of capacitors are well worth studying and following out by the design petroleum engineer in laying out the power supply facilities.

The author's statement relative to the pumping methods employed being something greater than 90 per cent with beam pump is correct, and since the greatest difficulty with this method is shutdown time on account of rod breakage, it is believed more information on this subject would have been interesting to review. For this reason, Figure 2 of the discussion is submitted to show the relative shutdown time for several groups of wells, for gas engine and electric motor operation.

These data cover a period of operation from April 1927 to December 1929, for wells of approximate depth of 2,800 feet located in Texas, equipped originally with single-cylinder horizontal gas engines and operating 24 hours per day. In order that proper comparisons could be made, three 3-month periods were selected and the results reduced to average monthly basis as shown graphically in the lower part of Figure 2 of the discussion.

The first period covers the operation of 109 gas engines for April, May, and June 1927. Following this period, the operations of the same wells were gradually being changed to electric-motor drive until April 1928, at which time there were 117 wells being pumped with electric motors. Therefore, the second period covers April, May, and June, 1928. One year's time elapsed in this transition period from gas engines to electric motors. The third period covers the operations during October, November, and December, 1929, and involves a study of 167 wells equipped with electric motors. The elapsed time was $1^1/_2$ years, between June 1928 and October 1929, which should be sufficient for the operators to become familiar with the new equipment. Only four gas engines were in use after April 1928.

It will be noted from Figure 2 of the discussion that the total down time per month per well was 32.02 hours for the first period, 21.2 hours for the second period, and 17.7 hours for the third period. The total down time for each well was broken down into down time for the various causes.

Under the cause "rods parted" the down time decreased from 12.5 hours per well per month, during the first period, to 4.47 hours during the second period, and 3.66 hours during the third period, the decrease probably due to being able to effect more accurate counterbalancing with the electric motors.

Another large oil-producing company submitted data regarding 47 single-cylinder, slow-speed gas-engine-driven wells and 206 electric-motor-driven wells located in the same field in Texas, pumping from a depth of approximately 3,000 feet.

These data are not carried out in detail for shut-down time, as shown in the lower part of Figure 2, but cover a period of several years from 1928 to 1930. The results of this study are averaged by the month and are shown in the upper part of Figure 2. Note that the hours "down time for pulling" appear in about the same proportion for gas engines and motors, as appear in the lower part of the figure under the caption "rods parted and tubing troubles."

The net results of both studies go to show advantages of the smooth electric-power application over the more or less pulsating power of the gas-engine application.

It is hoped that this discussion will in no way detract from the fine presentation made by the author in which he portrays the electric power uses for production of oil primarily from the equipment manufacturer's standpoint. Information regarding oil company operations, as submitted in Figures 1 and 2 of the discussion, is very hard to obtain, first, because they do not keep detailed records, and, second, because they do not care to expose their operations to the scrutiny of other people in their same business. For this reason, some of the information supplied in this discussion may appear too old, yet, in principle, the data are as good today as they were when taken, for the reason that production practices have remained rather static over long periods of time.

W. G. Taylor: Lamberger has called attention to two excellent refinements in the suggested methods of calculating well production and horsepower requirements. In consideration, however, of the facts that the results may be materially affected by the unpredictable amounts of sand and gas produced by the well, and that the assumption of volumetric efficiency of the pump may not always be close, it is questionable whether these refinements usually are warranted. No doubt the length of the stroke is the more important of the two, and although the production formula does not state this specifically as pump plunger stroke, that is the factor to use when data are available to determine it.

It is desirable that formulas for quick estimates be fairly simple. Great accuracy in this case would be inconsistent with the facts that some influencing factors are practically impossible to evaluate and that the standard motor size which must be selected is in most cases somewhat larger than the horsepower calculated.

Regarding induction motors with a slip of 5 to 8 per cent, commonly known as medium-slip motors, these are mentioned at the end of the section "Guide to Motor Selection for Beam Pumping." They came on the market for oil-well pumping at lower prices than high-slip motors of the same ratings, and have been attractive to the oil companies on that account. That they have been and are used successfully does not prove that they are the best motors for the purpose. The purpose of the slip is to utilize the stored energy in the rotating parts of the rig and motor to carry part of the peak load and thus reduce the current peaks drawn from the power system. As this stored energy is small, most of it being in the rotor of the motor, it is logically of most advantage to use as much of it as is possible and this is done by using the highest practicable motor slip. It is only by comparison that the user can readily appreciate the difference. However, there are probably cases where the medium-slip motor does well enough to satisfy the user, even if he knows the difference.

Stueve has added very materially to the information in my paper by the data and discussion which he has presented. It will be of great value to those interested in the subject.

Almost certainly a gas-engine man would claim that Stueve's data on engine shutdowns and rod breakage apply to a practically obsolete engine, which is true, but no data which I have been able to obtain on the high-speed multicylinder type of engine, now more generally used, indicate that any materially better results can be expected. Note particularly that Stueve points out that decrease in rod breakage with electric drive is probably due to the ability to effect more accurate counterbalancing with electric motors, and of course this has no connection with the type of engine used.

Full Utilization of Mexico's Hydraulic Resources Through Multiple Purposes

A. ORIVE ALBA

Available Water and Land in Mexico

CONTRARY to the current idea that Mexico is a country rich in natural resources is the fact that it is extremely poor in the two replenishable natural resources most vital to the economic development of any nation. These two resources are water and productive soil.

Rainfall is so scanty in 52 per cent of her territory that there exists no possibility of agricultural development without recourse to irrigation. Those parts of the country are referred to as arid zones. Rainfall in 31 per cent of the territory is distributed so unevenly that only occasional harvests are obtainable, thus requiring irrigation to assure them. Rainfall is sufficiently steady in 10 per cent of the remaining regions to assure agricultural development during most years. However, irrigation also is necessary and desirable in those regions to assure harvests during years when rains are scanty and to increase crops when the rainfall is abundant since, quite frequently, precipitation is not always even throughout those parts.

Summing up, we come to the conclusion that 93 per cent of our territory requires irrigation to guarantee agricultural development. Only in the remaining 7 per cent, which corresponds to tropical coastal sections of the states of Veracruz, Tabasco, and parts of Campeche and of Chiapas, are annual rains sufficiently abundant to assure agricultural production without recourse to irrigation. (See Figure 1.) These humid zones, potentially rich from an agricultural standpoint, are, however, unhealthy. To be able to explore and make them habitable, costly works in sanitation and drainage must be undertaken.

Mexico's mountainous topography, her climate and the quality of her top soil, in combination with factors of lesser importance, make it possible to estimate the amount of land that could be cultivated. It is estimated that this land does not exceed 60,000,000 acres (24,000,000 hectares) which represents 12 per cent of our total territory. However, harvests can be guaranteed only in a greatly reduced area which may be estimated reasonably as follows:

In 93 per cent of our territory where irrigation is necessary and which embraces the arid, semiarid and semihumid zones, the total utilization of river water in those parts permits only the irrigation of 17,500,000 acres (7,000,000 hectares) of land.

In the humid tropical zones which comprise 7 per cent of the nation's territory and where rainfall, as mentioned, is so abundant, the most optimistic estimates permit the conclusion that, after carrying out works of sanitation and drainage, only 7,500,000 acres (3,000,000 hectares) of land could be actually cultivated.

As a consequence, the estimated 60,000,000 acres (24,000,000 hectares) of land possible to cultivate must be reduced to 25,000,000 acres (10,000,000 hectares), leaving 35,000,000 acres (14,000,000 hectares) subject to cultivation only under the most fortuitous conditions, excepting such land as might be irrigated through the use of subsoil water. As yet, no close appraisal has been made of the extent of land that could be irrigated in this manner, but is estimated this will prove to be but a very small part of the total.

Paper 48-151, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted March 22, 1948; made available for printing, May 12, 1948.

A. ORIVE ALBA is Minister of Hydraulic Resources, Mexico, D. F., Mexico.

The Institute is indebted to the Mexico City Section for the translation of this paper from Spanish into English.

Significance of the Insufficiency of Water and Productive Land

The data just given are of vital significance to Mexico, a country that has at the present time 23,000,000 inhabitants with an annual population increase of a half a million. Assuming that all of Mexico's hydraulic resources were being fully utilized and that all requisite sanitary installations in tropical zones were already built, the nation would have only 25,000,000 acres (10,000,000 hectares) of land capable of cultivation, which means there would then be a coefficient of 1.07 acres (0.43 hectare) of productive land for each inhabitant. In the United States with a population of about 140,000,000, there are 400,000,000 acres (160,000,000 hectares) of productive land. The coefficient of such land is therefore nearly three acres (1.2 hectares) per person. This comparison indicates the inferiority of Mexico's agricultural possibilities in relation to those of the United States. To this disproportion we must add a consideration of the technical progress which has been made in agricultural development by the United States, itself an assurance of superior production per cultivated acre than that now obtainable in Mexico.

As has been indicated, the coefficient of 1.07 acres (0.43 hectare) per inhabitant constitutes the goal to be reached only when all the numerous installations necessary to a full use of Mexico's surface waters for irrigation purposes have been effected. At the present time, these installations are far from completion, thus the coefficient of land presently cultivated is considerably less than that of the aforementioned assumption. Actually, only about 5,000,000 acres (2,000,000 hectares) are now being cultivated through the use of irrigation and 15,000,000 acres (6,000,000 hectares) watered by rainfall. The total agricultural production of these lands is inadequate to meet the demands of the population, even of those basic food products such as corn and wheat. This deficiency in itself explains the low level of existence of the inhabitants of Mexico.

Figure 1. Climates of Mexico

Planning the Economic Development of Mexico

The government of Mexico, aware of the necessity to improve the food situation for the nation's population, has placed special importance upon the execution of great irrigation works. President Miguel Aleman has proposed the expenditure of 1,500,000,000 pesos, ($300,000,000, American dollars) for the construction of such irrigation works during his six year term of 1946 to 1952. This proposed expenditure will permit an increase of 2,500,000 irrigated acres (1,000,000 hectares). To appreciate the ambitious extent of the goal which the Mexican government has set itself to reach in the matter of irrigation, compare it with the history of the United States Bureau of Reclamation. Founded in 1902, during the first 30 years of its activity, the bureau had not spent $300,000,000 on irrigation, an amount less than 1,500,000,000 pesos, and, moreover, the land made available for cultivation by the bureau was less than that which our government intends to develop during the present presidential term of six years, terminating in 1952.

President Aleman has proposed projects for hydraulic and agricultural developments throughout all of Mexico, for the most part on arid land of insufficient agricultural productivity, in accordance with the following:

An increase of agricultural production of the nation to the maximum point compatible with her natural resources of water and land, to the end of meeting the demands of internal food consumption. The country should export, in some instances, tropical agricultural products, the volume of which exceeds the demands of internal consumption.

As Mexico can never hope to be a great agricultural country because of her paucity of water and productive soil, she should undertake through adequate co-ordination the exploitation of her other natural resources which exist in abundance, and fully develop the use of her raw products. This is imperative because the industrial development of the nation is its only possibility to establish an economically stable future.

These two purposes, harmoniously combined, provide a basis for defining the hydraulic policy of Mexico and should be the same for any country whose physical conditions are similar to our own. This definition of our hydraulic policy may be stated as follows:

All river water that flows through arid, semiarid, and semihumid regions of Mexico should be utilized to irrigate the greatest possible amount of land. It should be considered a grievous and inestimable loss to the nation to allow any of the river water that flows through land capable of cultivation through irrigation, to escape unused to the sea.

By taking advantage of dams and reservoirs and other installations to regulate the flow, the water of rivers should be used whenever possible to generate the maximum amount of electric energy before it is used for irrigation purposes, for, realizing the necessity of an industrial future for Mexico, we know that the best way to develop it is to enable the entire country to count upon an abundant supply of cheap power.

Examples of the Application of Our Hydraulic Policy

Arid, Semiarid, and Semihumid Zones

The aforementioned principles have served as a guide to formulate the projects we are carrying out to make full use of our river water, and to illustrate examples of what we are doing, we mention the complete utilization of the waters of the Cupatitzio river, which is a project of the Tepalcatepec Basin Commission, a branch of the Ministry of Hydraulic Resources.

This river has its source at springs located near the township of Uruapan, Michoacan, in western central Mexico. (See Figure 5). It has a uniform run-off, thus full use may be made of its water without recourse to reservoirs. By following the diagram of Figure 2 it can be observed that from its source to a point where it empties into the Casilda canal, the water level drops off approximately 3,610 feet (1,100 meters). Of this drop, 676 feet (206 meters) are already being used by the Cia Electrica de Morelia, and by the Federal Commission of Electricity, leaving a drop in the level of 755 feet (230 meters) which exists between an elevation of 4,540 feet (1,300 meters) above sea level at the foot of the Tzararacua Falls, and an elevation of 3,760 feet (1,150 meters) at a selected site for the construction of a diversion dam, for the installation of a hydroelectric plant in the near future. The magnificent natural beauty of the Tzararacua Falls precludes any industrial use being made of them as long as no imperative collective need exists, which at present is considered to be quite remote.

By constructing a diversion dam at a point called La Isla, the first step shall

Figure 2. Tepalcatepec River Commission Cupatitzio Development

have been taken to utilize the water of the Cupatitzio river. The elevation at La Isla divides in half the existing level between the Tzararacua Falls and Barranca Honda. Reserved for the future installation of Plant I, is the 755 foot (230 meter) drop in level already mentioned and which is shown in the diagram of Figure 2. By diverting the water at La Isla to Barranca Honda by means of a tunnel and a canal, a fall of 705 feet (214 meters) in the level can be utilized. With a normal run-off of river water of 606 second feet (17.2 cubic meters per second) it will be possible to develop 36,500 horsepower. Hydroelectric Plant II will be constructed there and will be a twin of Plant I.

Water discharged by this plant, which will be 198 second feet (5.6 cubic meters per second), will be used to irrigate important nearby agricultural zones. Drops in the levels of the irrigation canals will be used to operate secondary generating plants. A diversion of the water furnished by the diversion dam at Barranca Honda by means of a canal and a tunnel to El Salvador Barranca, will make it possible there to take advantage of a drop in level of 1,320 feet (403 meters) and, with a river flow reduced to 410 second feet (11.6 cubic meters per second), to develop 46,600 horsepower at Plant III. The water of this plant will empty into the Casilda canal and, together with the water of La Parota river and that pumped from the El Marquez river utilizing the power generated by Plants II and III along the Capatitzio river, it will be possible to irrigate 62,500 acres (25,000 hectares).

Figure 4. Papaloapan River Basin (Comision Del Papaloapan)

This project to utilize the Cupatitzio river water will permit the total utilization of that river's water together with that of other rivers and thus prevent any of the water to flow unused to the Pacific Ocean through the Balsas river. This example briefly represents the total utilization of water of a single Mexican river. An investment of 45,000,000 pesos (9,000,000 dollars) will be required to carry out this project but the following results will be obtained:

Irrigation of 62,500 acres (25,000 hectares) of rich soil and generation of 231,000,000 kilowatt hours. The annual return from the sale of power is estimated at $1,800,000 (9,000,000 pesos) and this alone would justify an investment of $14,000,000 (70,000,000 pesos). It may be concluded therefore that the project will not only pay for itself from a hydroelectric standpoint but will cover the necessary investments required for agricultural developments in that region, constituting thereby a group of works that realize both of the major objectives of the Ministry of Hydraulic Resources.

Figure 3. Nazas River Development

Another example that demonstrates how Mexican rivers may be utilized is the plan for taking advantage of the Nazas river in northern central Mexico (see Figure 5). The Nazas has its origin at an approximate elevation of 8,230 feet (2,500 meters) above sea level at the junction of the Ramos and El Oro rivers. Through the construction of the Lazaro Cardenas Reservoir which has a total capacity of 2,485,000 acre-feet (3,080 million cubic meters) and an active capacity of 2,105,000 acre-feet (2,600 million cubic meters), 80 per cent of that river's runoff is stored.

In this reservoir, the stored volume of water will permit the generation of 141,000,000 kilowatt hours once the 30,000 kw power plant, now being installed, is completed. At present, the water released from the reservoir is being used to irrigate 280,000 acres (113,000 hectares) of land in the region popularly known as La Laguna. The power generated at El Palmito hydroelectric plant will be used in part to pump sufficient water to irrigate an additional 125,000 acres (50,000 hectares). In this manner, all of the water of the Nazas river, before it reaches Lake Mayran is today being utilized to develop agriculture and to generate power. These installations will be perfected, through the construction of the Lomas Coloradas dam below the waters of the Lazaro Cardenas dam, a project planned by the

Figure 5. Location of the Nazas, Papaloapan, and Tepalcatepec River Developments

Ministry of Hydraulic Resources (see Figure 3).

The Lomas Coloradas dam will permit the hydroelectric plant at El Palmito to generate annually 150,000,000 kilowatt-hours in accordance with the demand made by the power companies in the States of Chihuahua, Coahuila, and Durango. Water discharged from El Palmito dam and Lazaro Cardenas reservoir will be stored and discharged later into the Lomas Coloradas reservoir as may be required for irrigation. Thus, full use of the water of the Nazas river will be made.

Utilization of River Water in Humid Zones

With regard to rivers that flow in humid, tropical regions where irrigation is not required, factors which define our hydraulic policy are reversed, for as no water is required to irrigate and, as in those regions there exists a marvelous perspective of securing a wealth of raw products, the first objective of installing hydraulic works should be the generation of maximum electric power and likewise, the other important purpose of controlling river courses through a regulation of the flow to ward off floods which often devastate whole sections of that part of the country when water is disproportionately abundant.

A good example in this connection, is the case of the Papaloapan, one of the great tropical rivers of Mexico. There is a project now under way, referred to as the Mexican Tennessee Valley Authority project, in charge of the Papaloapan Commission, another branch of the Ministry of Hydraulic Resources, which has as its aim to make use of that great river's waters.

Water of its tributaries which have their source in the arid parts of the states of Oaxaca, Veracruz, and Puebla will be used to irrigate agricultural lands of those states, but such water as is not used in this irrigation, as well as the water from other tributaries which the river receives in humid zones and where irrigation is not required, will be destined fundamentally, to generate power. For that purpose, enormous dams have been planned which will serve in a triple manner, the first being generation of power, second, control of the river's natural course to prevent annual floods that devastate not only productive lands of the lower Papaloapan but also villages located along its shores, and third, to facilitate navigation along the river (see Figure 4)

The basins of the rivers described may be seen schematically located in the map shown in Figure 5. Examples mentioned constitute but a part of the innumerable works being developed throughout the entire Republic of Mexico by the Ministry of Hydraulic Resources.

Objectives of the Ministry of Hydraulic Resources

So that the hydraulic policy, so tremendously important to a nation like ours, might better be materialized, President Miguel Aleman, at the time of his inauguration, created the Ministry of Hydraulic Resources, stressing clearly and precisely that such a policy cannot be eluded due to Mexico's physical reality.

Each of the examples cited is typical of what the nation is doing and proposes to do with every one of its rivers where hydraulic projects are being installed or where they should be executed. The most careful and conscientious studies are being made to improve the utilization of replenishable natural resources invaluable to Mexico due to her paucity of water. Irrigation and generation of power are considered to be the foundation upon which to build a glorious future for our country.

This desired goal will be reached when sufficient agricultural production has been assured to meet all achievable needs of the population. It will be possible only through co-ordination of the production obtained from reclaimed land with that of industry made vigorous through the abundant supply of hydroelectric developed power, well distributed and produced at such a low cost that it will be available to everyone.

We know that this policy of utilizing the hydraulic resources of Mexico to the utmost, to irrigate and generate power, is fundamentally the only adequate and even the only possible policy for a country that faces like physical and water problems, and whose soil characteristics resemble our own.

No Discussion

Hydroelectric Potentiality of Mexico

ANDRES GARCIA QUINTERO
NONMEMBER AIEE

THE amount of hydraulic power available in Mexico is ascertained by taking two essential factors into consideration, available water and waterfalls. The surface hydraulic resources of Mexico have been estimated to be 183,000 million cubic meters. This estimate is based upon the hydrometric measurements made by various government departments of basins that cover an area representing 38 per cent of the total area of the country. The major part of these basins is located in desert regions and in arid and semiarid sections. To estimate the mean annual runoff in humid regions, rainfall data, runoff coefficients, and areas of basins have been used and, to have a basis for comparison, some of the registered water measurements taken of the Usumacinta, Papaloapan, and Suchiate rivers. These data have proved of inestimable value in securing a truer conception of the water resources in those areas.

The other important factor or the difference of the levels that exist along the trajectories of our rivers until their waters are discharged into the sea or reach their final destination, compensates in part for the scarcity of water, for it is a well-known fact that the orographic formation of Mexico is characterized by the high central plateau which is bounded on the east by the Sierra Madre Oriental and on the west by the Sierra Madre Occidental while its southern tip is closed in by the massive mountain range called the Sierra Madre del Sur. Although some of the principal rivers of the country have their source in this plateau, the volume of water that flows along their trajectories is relatively small and nearly always of no practical value whatsoever during the low-water months of the year.

As precipitation is heaviest along the flanks of the mountains that face the oceans, rivers with the greatest amount of water have their headwaters there and, as these mountains are steep and often reach altitudes of 2,500 meters or more, extraordinary waterfalls are formed by the rivers that course down their sides to foothills and coastal plains averaging 200 meters above sea level. The volume of water of these rivers combined with their waterfalls creates enormous possibilities for hydroelectric development and generation of millions of kilowatt-hours.

Factors That Restrict Generation of Power

There are a number of factors that restrict the generation of electric power through the use of the Mexican river waters. They are:

Hydrological. In the first place, as mentioned, the flow of the rivers through the central plateau is very erratic. The same may be said of the flow of all rivers, for they derive their water in the main from the topographical rainfall. Storms bordering on cyclones frequently cause heavy rains and in the northwestern regions of the country, hot and cold masses of air during some of the winter months cause heavy precipitations. As a consequence, reservoirs have been found to be indispensable to regulate the natural flow. By storing up sufficient water during the rainy season, provision is made to regulate the flow during the low-water months of the year.

Table I. Power Installations Constructed in Mexico During Different Years

Year	Hydroelectric Plants, Kilowatts	Thermoelectric Plants, Kilowatts	Total, Kilowatts	Reference
1930	262,200	201,400	463,600	Herrera y Lasso
1939	389,100	291,300	680,400	General Director of Electricity
1943	397,100	283,000	680,100	General Director of Electricity

Paper 48-152, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted March 19, 1948; made available for printing May 12, 1948.

ANDRES GARCIA QUINTERO is with the Ministry of Hydraulic Resources, Mexico, D. F., Mexico.

The Institute is indebted to the Mexico City Section for the translation of this paper from Spanish into English.

Second, since it is not economically feasible to construct dams to store up all the water of the rivers when rainfall is heavy, much of it is lost through spillways, a fact to which one has to be resigned. Evaporation losses furthermore reduce the disposable volume. Thus, only a maximum of 75 to 80 per cent of the natural runoff can be utilized.

Topographical. Though differences of the levels of the Mexican rivers are often tremendous along short, steep stretches, these differences unfortunately cannot be utilized 100 per cent, as dam construction requirements, reservoir capacities, canals, and derivations cause significant reductions of the total head. The gross potential head is reduced furthermore by friction losses, intake, elbow, and pipe losses. It is therefore estimated that only 50 per cent of the available total potential head can be utilized.

Other Restrictions. There are other factors that contribute to the reduction of the theoretical power which could be developed through the use of river waters, such as the combined efficiency of hydraulic and electrical equipment, demand characteristics and length of transmission lines. An average efficiency of 75 per cent is what may be expected when all these factors are taken into consideration.

How Mexico Has Utilized Her Hydroelectric Resources

Mexico has just started to develop her potential hydroelectric resources. In fact, as will be observed, Mexico has utilized to date less than one-tenth of all her hydroelectric resources. Taking into consideration available statistical data, the chronological summary of hydraulic potentialities shown in Table I was drawn up.

Hydraulic Power Available in Mexico

The only logical way to estimate the hydroelectric potentialities of Mexico is to estimate and directly measure her surface water resources, to precisely know her topography in order to determine what the most feasible sites are where power can be generated. The generation of power then is subject to:

1. Storage of water in reservoirs.
2. Capacity of reservoirs.
3. Conduction of water to site of utilization.
4. Construction of the power house.

It should be remembered that Mexico is a country so deficient in water that she requires, for an assured agricultural development, the irrigation of her arable lands in 93 per cent of her total area. This leaves only 7 per cent of the territory in which natural humidity makes irrigation unnecessary in the arable land, and where it is possible therefore to employ all the surface waters to generate power.

Experience gathered through our work as hydrologists in the Ministry of Hydraulic Resources allows us to make a tentative estimate of the magnitude of hydroelectric potentialities of Mexico. This estimate is shown in Table II.

Table II shows that it is possible to dispose of approximately 13,176,000 horsepower of potential water power in the whole country. However, taking into consideration the reduction of water resources through the continual increased utilization of water for irrigation and other purposes, we must acknowledge that only about 9,785,500 horsepower are available for hydroelectric development or 25 per cent less than the estimated potential total.

Table III. Horsepower Potentials of Several Countries

Country	Horsepower Potentialities
Africa (Belgian and French Congos)	124,664,879
United States of America	41,689,008
India	26,809,651
China	20,107,239
Canada	17,963,466
Russia	15,951,743
Mexico	9,785,523

Mexican Resources as Compared with Those of Other Countries

In order to gain an insight into how the Mexican hydroelectric potentialities compare with those of other nations, their estimates are given in Table III.

At present, Mexico's hydroelectric installations total a capacity of 511,000 kw; with a mean annual demand of 250,000 kw. As the estimated total potentiality amounts to 9,785,523 horsepower which will represent a mean annual demand of 7,300,000 kw it is deduced that Mexico up to the present has only developed but 3.4 per cent of her hydroelectric resources.

Required Installations

Considering that two kw need usually to be installed to take care of an average one kw demand, installations totalling 14,600,000 kw are required to take full advantage of Mexico's hydroelectric potentialities. As only 684,987 horsepower have been developed, there remain yet to be built, installations with a total capacity of 18,886,059 horsepower to supply the balance of 14,089,000 kw. It is estimated that a capital investment of 9,862,300,000 pesos or $2,000,000,000 (American dollars) will be required to construct these installations.

No Discussion

Resistance-Welding Machine and Power Supply

C. E. SMITH
MEMBER AIEE

THE PURPOSE of this paper is to acquaint the reader with the various types of resistance-welding machines, their correction devices, and their effects upon the power supply systems.

The installation of these various types of welding machines is dependent upon the following.

1. The ability of the machine to be installed without creating a cyclic flicker disturbance on the high line regardless of the customer's present power-supply system.

2. The effects of the installation in consideration of over-all cost with a thorough study of the type of equipment which would prove the least expensive. The cost of the proper distribution system, if the high-line supply is inadequate to take the instantaneous demand created by the various types of welding machines, must be analyzed carefully against the cost of individual correction devices.

A thorough study must be made to each individual installation or proposed installation as to the proper types of machines and the cost of these machines to produce an installation of the most economical value. Therefore, the cost of these various systems known at the present time must be given consideration.

3. Various correction devices considered in this report with their departure from the fundamental wave shape of 60-cycle current or supply-line current and the effects of various secondary wave shapes in the welding of the material are given consideration.

It appears at this time that the single-phase a-c machines, uncorrected, are the machines for general application wherever the power supply is adequate. In other words, if the installation of a group of a-c, uncorrected, single-phase machines could be installed without creating cyclic flicker nuisance values, the a-c single-phase machine is still the machine to recommend. Wherever the power supply is inadequate to handle regulation imposed on the system, a thorough study must be made according to the number of machines being installed and the present cost of reinforcing the system versus the various types of direct and indirect-energy types of machines available at the present time.

When large and intermittent single-phase loads produced by resistance-welding machines are taken from a 3-phase system, an unbalanced current distribution results which is generally undesirable.

1. Lowered apparatus economy of transformers, lines, distribution system, and generator.

2. Lowered over-all efficiency.

3. Line voltage distortion, or unequal voltage regulation resulting from unequal loading on the three lines.

Various transformer connections and other electric equipment have been proposed in the past either to lower the kilovolt-ampere demand of the machines, equalize the distribution of the single-phase current over a 3-phase system, or both.

For the purpose of readily comparing one or more of these systems with another, they have been arranged in two groups, direct and indirect energy types (Figure 1).

Direct-Energy Types of Equipment

A-C Single-Phase Welding Machines

The fundamental design of the resistance-welding machine, particularly the necessary secondary configuration for work clearance, makes the reactive component of current relatively high, giving the machine a high kilovolt-ampere demand and a low power factor. Since the welding machine is in reality a transformer with a low-impedance load, the current from the line contains two components, one in phase with the voltage and one lagging. Thus the welder is made up of a large reactive kilovolt-ampere component and a resistive-kilowatt component. The kilowatt component supplies the necessary power to make the weld and also the losses of the machine. The application of heavy-duty welding machines, with large and intermittent demands produced on the supply line, may create a cyclic flicker that becomes a nuisance to the power server and users of this equipment with the result that the utility engineer is tempted to discourage this type of a load, or to force some other solution to the problem. The sudden and repeated flow of current to the welder through the impedance of the supply system causes an intermittent voltage drop, which if great enough in magnitude, may cause objectionable flicker of the lamps of the lighting system fed from the same portion of the system. Two types of lamp flicker may be created by resistance-welding machines; a noncyclic flicker from single-impulse machines such as spot, butt, flash or projection welders, and a cyclic flicker from seam welders or spot and projection welders equipped with pulsation control.

Acceptable Voltage Drop

If the lamp voltage drops more than two volts out of 115 volts, the noncyclic flicker is usually objectionable to the lighting customers.

If the frequency of current flow exceeds one impulse a second, this cyclic flicker becomes evident and may prove objectionable. Here the borderline of objec-

tion or irritation follows a typical V curve, as shown in Figure 2, dropping to a minimum of about 1/2 volt at the worst frequency of seven or eight impulses per second.

When the economics of the final solution of installation of a welding machine in regards to the utility problem dictate the correction of the welding machine load itself, there are various ways of attempting to lower the kilovolt-ampere demand of that particular welding machine.

Series-Capacitor Power Factor Correction Equipment

Series-capacitor power-factor correction applications have been numerous and very successful, and with the present engineering information available for calculation of the necessary capacitors to correct a given welding job, it makes it a rather simple problem. Besides being expensive as a correction device, the series capacitors have definite disadvantages in that a certain turns ratio of the transformer must be as selected and adhered to, making it more or less applicable to one job at the same optimum conditions, unless the welding manufacturer is informed of the range of work which the machine is expected to do. In some instances, machines have been corrected with series capacitors which will correct the kilovolt-ampere and the power factor during the welding of aluminum, and by means of selector switches inserted to change the turns ratio of the welding transformer, make it possible to weld mild steel, and in some instances, stainless steel that requires a wide range of secondary current. Figure 3 shows an elementary circuit and the voltage vectors of a corrected, an under-corrected, and an overcorrected series capacitor system.

One of the arguments used against series capacitors has been that the machine must remain at approximately the same secondary configuration, and that if the throat areas change, it is necessary that an expert be available to revise the tuning or determine the correction of the circuit to bring it back to approximate unity power factor. However, if the welder machine is so designed with a maximum of throat configuration necessary for the job, and consideration given to the future applications of the job that the customer expects to weld in the future, the series-capacitor equipment becomes in some instances less expensive with a large throat machine than a small throat machine. Therefore, the maximum demand has been correct, and as the power company can serve such a demand, there is no reason why the secondary configuration should be changed.

The series-capacitor power-factor device at this time is the only device known to be economical and practical for achieving a unity power-factor load.

Another reason that may increase the cost of the series-capacitor power-factor correction-equipment installation is the cost of the control panel. This panel may be of the 2,300-volt variety, or out of the class of the standard 600-volt a-c controls. Another alternative is to make use of an autotransformer to reduce the input line voltage to a low value wherein the capacitor voltage plus the line voltage does not rise to over 600 volts, so that the ignitron contactor and nonsynchronous type of equipment can be used along with the standard 440 welding transformer primary. Figure 4 shows the kilovolt-

Figure 5. Shunt capacitor power factor correction circuit

ampere demands of a corrected and an uncorrected machine producing the same secondary currents.

Shunt-Capacitor Power-Factor Correction Equipment

Shunt capacitors have been used very successfully with many more or less constant load applications for many years, and it is a type of power-factor correction with which the utility engineer and most electrical engineers are familiar. Since the load in a resistance-welding machine is of a highly intermittent nature, the problem of power-factor correction with shunt capacitors is unusual as compared with ordinary power factor correction problems. The first thought that comes into the engineer's mind for correction of a resistance-welding machine is by the use of shunt capacitors across the primary of the welding transformer. The operational duty cycle of welding machines is quite low with the off-time periods allowing the shunt capacitors to discharge through the primary of the welding transformer. Due to the dead short-circuit characteristics of the capacitors, the inrush of charging current prohibits this type of correction.

It is possible to eliminate the charging-current inrush to the shunt capacitors by precharging them to the correct voltage and connecting them in parallel with the welder primary synchronously and simultaneously with the closure of the primary circuit to the power-supply feeder. This circuit is shown in Figure 5. It requires a standard synchroncus control in series with the welder load along with auxiliary devices for synchronous closing of the shunt-capacitor current and the precharging circuit. One pair of tubes permits the precharge of the capacitor by disconnecting it from the welder primary, and the other pair of power tubes acts as a synchronous switch on the supply circuit to control the welder in the conventional manner. This arrangement requires two sets of power tubes and a precharging circuit which are generally expensive in relation to series-capacitor circuits.

Another application of shunt capacitors can be as shown in Figure 6 wherein the shunt capacitors are connected permanently across the supply feeders as close to the welding machine input leads as possible. The disadvantage of this type of correction is that during the idle or no-current flow period of the welding machine, the device will attempt to overcorrect the supply line according to the auxiliary load on these lines. If however, a device is applied to the shunt capacitors that will prevent overcorrection or overvoltage of power-supply lines, the application may have considerable merit. A thorough study must be made before application of such devices to a large number or group of welding machines with consideration given to the customer's supply-line impedances. A suitable reactor for cancelling out the fifth and seventh harmonics that are developed due to the transformer and capacitor type of circuit is worth considering since the fifth and seventh harmonics in this type of a circuit can create considerable power losses. With the elimination of the fifth and seventh harmonics, more correction kilovolt-amperes can be obtained from a standard-kilovolt-ampere capacitor unit.

Figure 7. Vector diagram showing improvement of voltage

E_S—Line supply voltage
E_R—Welder load primary voltage
E_{S1}—Readjusted line voltage required after compensation to give same E_R
E_{S2}—Supply voltage required after compensation for resistance and reactance drops to maintain same E_R

To tune the circuit to approximately unity power factor with any shunt capacitor method becomes quite expensive and the installation is generally corrected to approximately 85 per cent power factor and thus falls within economical ranges. If the power factor of the load is 50 per cent or higher, the shunt-capacitor application may be less expensive than the series-capacitor application. However, if the power factor is 50 per cent or lower, the series-capacitor application may be less expensive.

Series Capacitors in the Supply Line

Installation of series capacitors for power-factor correction of resistance-welding machine in the welder circuit has been discussed. The voltage regulation problem because of the high and intermittent variations of the amount of cur-

Figure 6. Shunt capacitor power factor correction of single phase a-c machine

Figure 8. Voltage chart illustrating voltage regulation for resistance welders

rent created by the resistance-welding machine has been pointed out. Since the welder is operated at a low power factor, these current variations may cause large variations in the voltage drop across the system impedance. It is possible to reduce these voltage drops either by reducing the welder current, or by reducing the system impedances. With the series capacitors at the individual welders, the capacitor reduces the line current by improving the welder power factor. As a result, the voltage drop across the system reactances are reduced and the voltage regulation is improved. This scheme is particularly desirable where the welder load is made up of a few large welders and the diversity factor is low.

If the welder load is made up of a large group of welders and the diversity factor is high, it is often economically advantageous to install series capacitors in the supply line, and thereby take advantage of the higher diversity factor. Figure 7 shows the capacitors installed in this manner for improving voltage regulation by neutralizing the system reactances. The vector diagram illustrates the improvement of voltage regulation by this system. By proper capacitor selection, it is possible to hold the voltage regulation within very narrow limits.

Generally the series capacitors are installed in the line immediately ahead of each load center unit. The bus voltage is not constant and varies because of fluctuations in load current which causes variation of the voltage drop across the system reactances between the power source and high-voltage bus (the system reactance is made up of two main components, the utility-system reactance and the reactance of the transformer between the utility's high line and the high-voltage bus). The utility-system reactance is practically constant, but the transformer reactance will depend upon the number of transformers in service. It is not desirable to install any capacitors in the welder feeders supplying a group of welders because of the variations in reactance which

Figure 10. Ratio of single-phase kilovolt-amperes to 3-phase kilovolt-amperes (metallic rectifier) on size three R.W.M.A. press welder

they would be called upon to cancel, and because it is desirable to maintain the high-voltage bus voltage essentially constant to the benefit of other connected loads. Hence, the capacitors should be installed in series with each step-down transformer between the distribution transformer and the high-voltage bus. As additional transformers are added for additional service, an additional capacitor unit can be provided.

Even though every care is taken to select the proper capacitance values, it is not possible to calculate the system reactance exactly. For this reason, provision is made for tuning the capacitors in the field, simply by adding or removing units. By tuning the capacitors, system reactance can be matched very closely.

The over-all voltage regulation is illustrated by the voltage regulation chart, Figure 8. Without series capacitors, the welder voltage drop will be approximately 20 per cent under peak-load conditions. With the series capacitors installed, the small voltage drop of the welders will be due almost entirely to the system resistance.

Metallic Rectifier (Magnesium Copper-Sulphide Type)

A 3-phase metallic rectifier capable of delivering direct current into the secondary of the welding machine makes it possible to produce a 3-phase lower kilovolt-ampere demand than the conventional single-phase welder and is one answer to the problem of lowering the high demand usually found in the single-phase a-c welding machine. This type of welder can be a seam, spot projection welder or flash welder. The rectifier stacks have an exceptionally long life, are small in size as compared to other types of electrical components and are of rugged construction. These rectifiers are very suitable to a welder load, being capable of supplying heavy short-time current overloads, with power consumption at no-load practically nil. For the most economical transformer design and most satisfactory rectified wave form for the particular d-c output voltage and current required in a resistance-welding machine, the rectifier circuit should be 3-phase full wave. (Figure 9).

The metallic rectifier type of machine uses rectifier transformers instead of a welding transformer and with the 3-phase full-wave circuit, is much more efficient and economical in comparison with the 3-phase half-wave circuit. The kilovolt-ampere demand will generally be less to make a given weld in comparison to alternating current, or any frequency conversion system and since the welding current is direct current, the effect of the secondary configuration is less noticeable as to reactive electrical losses. Figures 10 and 11 show a comparison of the 3-phase kilovolt-ampere demand of a metallic rectifier machine with the single-phase kilovolt-ampere demand of an a-c machine producing the same secondary currents. The kilovolt-ampere figures for the 3-phase machine are the line current times the line voltage times the square root of three.

Due to the values of resistance and inductance usually found in a welding

Figure 9. Three-phase full wave circuit of d-c metallic rectifier

Figure 11. Kilovolts-amperes demand single-phase alternating-current and 3-phase direct-current versus throat depth

Size three R.W.M.A. press welder

Figure 12 (left). Electronic frequency converter system, 3-phase half wave

Figure 14. Ratio of single-phase kilovolt-amperes to 3-phase kilovolt-amperes (frequency conversion) on size three R.W.M.A. press welder

machine, the rate of rise of current in a metallic rectifier machine is rather slow, making it particularly desirable for projection and upset-butt welding. The current actually rises faster than the calculated static values of R and L would ordinarily permit, due to the fact that the rectifier resistance changes during current rise. At the start of current rise, the applied voltage makes the current start in such a manner as though the apparent maximum current would be about twice the actual maximum. Approximately eight milli-seconds after start of current flow, the voltage decreases to a low constant value reducing the overshooting tendency of the voltage and current rise.

One factor requiring consideration in the application of metallic rectifiers in welding machines is the proper analysis of the efficiency. A study of the impedance curve and the efficiency measurements will show that the efficiencies are lowest at low currents and with low-impedance loads. With a given load impedance, the efficiency improves as the current increases. With a given current, the efficiency will improve as the load impedance increases up to a point where the load impedance equals the rectifier impedance. In resistance-welder applications, there is no object in attempting to operate the rectifiers at a maximum efficiency as long as the impedance adjustment must be in the load circuit, not in the rectifiers themselves.

Since the rectifier units are essentially resistance devices, the power factor will be between 90 and 100 per cent, and the primary current wave is without the discontinuity which is present when using rectifier tubes. The distortion of the primary current wave is negligible. With the use of the 3-phase full wave circuit, it can be stated that the primary current will be balanced almost perfectly.

Electronic Frequency-Converter System

The use of electronic frequency-converter systems to reduce the frequency of the secondary current to a low value, thus reducing the inductive reactance of the secondary loop circuit has merit as to the reduction of the kilovolt-ampere demand. At the present time, there are two types of rectifier circuits being used by one resistance-welding manufacturer and these circuits are shown in Figures 12 and 13. By eliminating the rectifier transformer (shown in Figure 13), Figure 12, and making use of a 3-phase welding transformer with the ignitron tubes properly connected for 3-phase half-wave rectification, this type of converter becomes practical as a correction device. The welding transformer must be designed for the very-low frequencies (5 to 10 cycles), and therefore, much larger than a 60-cycle transformer of comparable rating. The electronic frequency-changing circuits draw almost balanced 3-phase power from the line and have a low-frequency single-phase output. The power demand is not perfectly balanced on the three phases due to the nonsinusoidal nature of the current wave. Double advantages are secured from such an electronic circuit because the power factor increases when the load is operated at a low frequency, and the ratio of 3-phase kilovolt-ampere demand to single-phase kilovolt-ampere is approximately four-to-one in the deep-throat machines. Commutation faults, however, must be given consideration with the introduction of a low frequency system since during one or more cycles (on supply frequency basis) the entire load is single phase, resulting in a momentary increase in voltage drop of two lines. This momentary drop may have a very small value when read on an rms meter, but it may

Table I

Case	Number of Welders	Type of Welder	Assumed Voltage Drop*
1A	1	3-phase metallic rectifier, or electronic converter type of welder	1 per cent
1B	3	3-phase metallic rectifier, or electronic converter type of welder	
2A	1	1-phase, series-capacitor power factor corrected**	1 per cent
2B	3	1-phase, series-capacitor power factor corrected**	
3A	1	1-phase, uncorrected alternating current (Correction factor 3 to 1)**	3 per cent
3B	3	1-phase, uncorrected alternating current**	

* Same supply system in all cases.

** Phase control, if any, set at 100 per cent heat.

still cause objectionable lightflicker. The only drop that must be considered in analyzing the possibility of lightflicker is the drop on the load-phase line. Figures 14 and 15 show the comparison of the 3-phase kilovolt-ampere demand to single-phase kilovolt-ampere demand producing the same secondary currents.

One of the improvements that can be made to the converter system is to close up the zero-current gaps during the transfer, or change in polarity of secondary current. With the introduction of zero-current gaps during current flow, the impulses per second or flickers per second may fall in a range of approximately nine per second, or within the 1/2-volt limit, commonly termed as cyclic-flicker range similar to pulsation or seam welding on and off timing periods.

The frequency-converter system is somewhat likened to the metallic rectifier in that, since it is a high-power factor device, (approximately 85 per cent) it is resistance limited and generally no-current compensation is required or any correction necessary for the introduction of magnetic material in the throat of the welder machine.

Rotating Equipment

To offset an inadequate power supply, motor-generator sets have been used, but due to their original cost, maintenance cost and their short-time transient regulation, they have not usually proved satisfactory. To offset the first two disadvantages, a large motor-generator set is generally employed to handle a group of welders, but the transient reactance with simultaneous operation of the machines makes this system generally undesirable.

A motor-generator set, with 3-phase input and single-phase output of commercial frequency or low frequency, may have satisfactory application to a single machine, that is, one motor-generator set per machine.

The possibilities of designing a motor-generator set with a generated direct current may have possibilities in the application of resistance-welding machines. The original cost of such equipment and the problems of commutating, collecting and making and breaking heavy secondary currents may be objectionable. Since many welder loads have operating duty cycles in the order of 5 to 10 per cent, the no-load losses of the motor-generator set during the remaining 90 to 95 per cent of the time may affect over-all efficiency.

The use of a fly wheel with a motor-generator set may give it some characteristics of an indirect-energy (or stored-energy) welder.

Transformation by Means of Transformers

The most common transformation is the connection of a single-phase load to a 3-phase line, and many attempts have been made to do this to obtain a balanced 3-phase load. The only method that is known at the present time is to divide the load into three equal parts and connect one part to each phase. This method is desirable and often practical. There are, however, many different methods of obtaining a single-phase voltage from a 3-phase system by using transformers and which result in varying distributions of the current in the 3-phase system. Of all these connections, the "Scott," Figure 16, is the most suitable for usage in conjunction with welding machines. The data taken from one installation showed that if a straight single-phase connection resulted in a 4 per cent line in voltage drop, during the weld on the one leg of a 3-phase line to which the welder was connected, 2 per cent on one of the other legs and 1/2 per cent on the third leg, the use of an auxiliary "Scott" transformer and connector would result in approximately 2 per cent voltage drop on two legs and approximately zero drop on the third leg. It can be seen from this that the voltage drop on the line to which the welder was connected was cut in half, a considerable improvement.

This "Scott" connection cannot result in a balanced 3-phase load. The single-phase voltage applied to the welder from the transformer is 0.866 times the standard line voltage; to obtain proper output, therefore, the welding transformer must be especially wound to operate on 86.6 per cent of the line voltage, and the welding-power control equipment of the synchronous type must be operated from the same reduced voltage. One of the schemes, shown in Figure 16, is the most commonly suggested and the values given with the diagrams are those based on a one-to-one ratio of transformation. Since the voltage at the primary of the welding transformer is reduced by 0.866, the primary current will be increased by 1.15, if the machine is to produce the same secondary currents.

The apparatus economy is the ratio of the maximum kilovolt-amperes which the bank can deliver to the total kilovolt-ampere of apparatus making up the bank. Tables I and II give the characteristics of these connections and show that they are generally inferior to a single-phase transformation. By straight single-

Figure 19 (left). Formulas

Figure 20 (right). Wave shapes of electronic frequency converter

phase connection of one transformer between two wires of a 3-phase system, the total value of power delivered is the same in all cases. The only advantage that the "Scott" scheme has will be noted that the delta-connected generator has a maximum current of 0.577 as against 0.667 of the straight single phase. To offset this, however, this scheme required two transformers possessing greater total capacity and also impose upon one line a greater maximum current.

Regulation Characteristics of 3-Phase and Single-Phase Machines on 3-Phase Lines

One interesting feature of the regulation characteristics of 3-phase machines versus single-phase machines on a 3-phase line is shown in Figure 18. The regulation of a 3-phase dry-disk rectifier machine, or a 3-phase electronic-converter machine under an assumed regulation of one per cent on the system (with these assumed voltage drops caused by one welder of each type, or agreed to be reasonably typical for machines of each type to do the same welding job on the same power system) will produce three per cent regulation with three machines of the 3-phase type, but only $1^1/_2$ percent regulation with three series-capacitor power factor corrected machines distributed around the three legs of the 3-phase system. Figure 18 also includes the regulation of the uncorrected single-phase machine distributed around the 3-phase system with the assumption that the correction factor is three-to-one.

A given kilovolt-ampere of a 3-phase load causes one-half as much as percentage rms voltage drop as the same kilovolt-ampere of a single-phase load. This is proved in Figure 19.

In the illustrated cases using 1-phase welders in Figures 18 and 19, the maximum drop created by three welders is only $1^1/_2$ times the drop due to one welder. This may be explained also by the use of the well-known rule that a given kilovolt-ampere of 3-phase (sine wave) load causes half as much maximum rms voltage drop as the same kilovolt-ampere of a single-phase load. Hence, although the kilovolt-ampere is increased by three, distribution of the single-phase welders on the three phases makes this load three phase. Therefore, the drop is three over two of its value for a single 1-phase welder as shown in Figure 19.

Table I illustrates the voltage drops created by one welder, and Table II illustrates the voltage drops created by three welders.

Table II has the following conditions assumed:

1. Welder types are as given by Table I.
2. Voltage drop for any one welder is as given by Table I.
3. Single-phase welders placed each on a different phase (line to line).
4. Same supply system in all cases.
5. Voltage measurements taken in the same place in all cases.
6. No Y-delta transformation between load and voltage measurement point.

Assumptions for Voltage Drop Rule*

1. Positive and negative phase sequence and impedances of supply system are equal.
2. Voltage drop is a small fraction of the total voltage.
3. The maximum voltage drop, due to the 1-phase load, occurs on the loaded (line to line) phase.
4. Same supply system at all times.
5. Impedances are constant.
6. Currents are sine waves at operating frequency.

The foregoing includes the assumption that the maximum voltage drop due to a single-phase load occurs on the loaded phase. For certain combinations of uncorrected welder power factor and supply system, X over R ratios, the maximum-voltage drop due to a series-capacitor corrected welder may occur on a different phase. However, in such instances, the drop per case $2B$ (three welders) will be less than as given by the rule. In these instances, the voltage drop caused by three such welders (at 100 per cent phase-control setting) may even be less than for one, if the system X over R ratio is sufficiently high.

Primary Wave Shapes of Rectifier Circuits (Metallic Rectifier and Electronic Frequency Converter)

A polyphase system or circuit is said to be perfectly balanced when conditions in all phases are the same, that is, when the voltages across all the phases, the currents flowing in all the phases, and the power factor of all the phases are the same. When any one of these quantities is not the same in all phases, the system is said to be unbalanced.

An investigation of rectifier circuits is primarily a study of wave forms. Unlike rotating apparatus, a rectifier stores no energy within itself, and there is a constant connection between voltages and currents on the a-c side and voltage and currents on the d-c side.

The voltage at the primary terminals of a rectifier is sinusoidal while the current is nonsinusoidal. It may be resolved into a number of sinusoidal components consist-

Table II. Voltage Drops Created by Three Welders

Case	Maximum Voltage Drop, Per Cent
1B	3
2B	$1^1/_2$
3B	$4^1/_2$

* A given kva of a 3-phase load causes one-half as much percentage rms-voltage drop as the same kilovolt-amperes of a single-phase load.

ing of a fundamental wave of the voltage frequency and of the higher harmonic waves which are multiples of the fundamental frequency. The rms value of the line current is the square root of the sum of the squares of the component currents. Only the fundamental component of the current carries power; the higher harmonic components cannot carry power as there are no voltages of corresponding frequency.

Figure 20 is a wave form of a 3-phase half-wave rectifier circuit and a 3-phase double-wye paralleled rectifier circuit.

Primary Power Factor of Rectifier Circuits (Electronic Frequency Converter and Metallic Rectifier)

The power factor is similar to any rectifier using a 3-phase half-wave circuit, or a 3-phase double-wye paralleled circuit.

Under ideal conditions, the power factor is the square root of two times the utility factor, or

$$\text{Power factor} = \frac{2\sqrt{P}}{\pi} \sin \frac{\pi}{P}$$

P = number of phases

The double-wye circuit, Figure 13, will give a higher utility factor than the 3-phase half-wave circuit (Figure 20). It is interesting to note that in the double-wye circuit or the 3-phase full-wave circuit (where mentioned and calculated), windings will be almost as effectively utilized as though they carried sine-wave current.

The ratio of watts to volt amperes is a somewhat complicated function as it consists partly of an out-of-phase component and partly of a component due to the distortion of the wave form. Even on a resistive load there is a form factor due to the current not being continuous. The current ceases to flow during the period that the transformer voltage is below that of the arc-drop voltage of the tubes. The rectified wave form is not a true sine wave.

An inductive load (there is always inductance in the circuit either in the supply line, or leakage reactance at the transformer and leads) also affects the power factor by both decreasing the form factor as well as the angle of the lag.

It is interesting to note that the form factor has a very useful effect on improving the over-all power factor of the system. In other words, connecting a rectifier to a system improves the over-all power factor of the system. In particular, the wattless input of the rectifier cannot be added algebraically to the wattless input of reactive equipment for all of the harmonic components but must be added at right angles. The true power adds directly to the system, while the fictitious power being largely harmonics, makes no appreciable addition to the reactive power already carried.

Indirect Energy Types of Machines

The electrostatic (capacitor), the electromagnetic (reactor), the mechanical (rotating equipment with flywheel) and the electrochemical (battery) systems are systems where the energy to make a weld is stored during the no-weld period and released during the weld period. The energy control devices are generally 3-phase input units.

The kilovolt-ampere demands of these systems are shown in Figure 21 in comparison to a single-phase a-c machine to do an identical welding job (aluminum).

Although these devices limit the kilovolt-ampere demand on the supply lines, application of the machines must be given consideration as to the ability of welding certain materials. The electrostatic and electromagnetic machines with their rapid rate of current rise and type of wave shape are more suitable for the welding of aluminum and magnesium alloys in the commonly used range of thicknesses.

Figure 22 gives the secondary wave shapes of the various types of machines discussed in this article. The time to maximum, T maximum, rate of rise of current and wave shapes are representative illustrations only. The electronic frequency converter, the motor-generator type, and metallic rectifier wave shapes are fixed by the total R and L, and the regulation of the systems. The battery welder, Figure 23, has a variable resistor for controlling the value of the welding current, and pressure changes on the carbon contactor (together with the R and L of the rest of the circuit) vary the rate of rise of current. The battery welder has a wave shape similar to that of the metallic rectifier.

In addition to R and L of the circuit, the electromagnetic system, Figure 24, in some instances has alloy blocks inserted in the secondary circuit for changing the wave shape.

An important feature of the capacitor stored energy machine, Figure 25, is its ability to deliver a current wave shape of almost any desired rate of rise through adjustments of the welding transformer turns ratio, the amount of capacitance variations of the capacitor voltage give close control over the energy to make the weld.

Effect of Secondary Wave Shapes in Respect to Welding

Frequency converter, metallic rectifier machine, motor-generator type, and battery welder:

Advantages

1. In projection welding or upset welding nonferrous alloys, the current rise is slow and peak current in relation to rms is low enough to prevent blowout of material at start of weld.
2. In spot or seam welding heavy sections

Figure 21. Kilovolt-amperes demand of single-phase machine, magnetic-stored energy machine, capacitor stored energy machine, and battery machine

Size three spot welder. Machines equivalent in ability to weld same material at approximately the same rate of operation

Figure 22 (right). Secondary current wave shapes of direct and indirect systems

T Maximum—time to maximum current

Figure 23. Electrical circuit of battery welder

Figure 24. Electromagnetic stored energy systems

Figure 25. Elementary diagram of electrostatic stored-energy system

of aluminum, the rate of rise of current is slow enough to permit electrodes to follow and heat before electrode burning occurs. This is a decided advantage over 60-cycle a-c welding.

3. It is possible to make the weld, in heavy aluminum sections, over a longer period of time than on the electromagnetic or capacitor stored-energy systems where the weld must be made in the region of peak current. With the travel of heat in the material and the nugget forced to grow fast, spitting sometimes occurs before the nugget has fully grown when welding with stored energy.

4. The slow rate of rise of current will produce more consistent joints in aluminum with inconsistent cleaning or commercial uncleaned aluminum than in comparison to a-c or stored energy of the capacitor or magnetic type.

5. There is no need for current compensation due to magnetic material changing its position in the throat of the machine.

6. Double-pressure timing need not be so accurate.

Disadvantages

1. Low frequency will be detrimental in shunt currents in adjacent welds. Since the impedance between spots changes with the frequency, very careful consideration should be given to shunt currents created by adjacent spots.

2. In comparison to the metallic, battery machine or motor-generator set (alternating current to direct current) and their continuous current conduction in respect to the envelope wave shape of the frequency current converter and with zero current gaps during secondary current change in polarity, the weld time will be longer or more heat is required. For every cycle of zero current gap, it will require a cycle of full current to regain temperature in the weld equivalent to the temperature at the end of the preceding weld. This leaves the balance to steady-state current or maximum current at the end of each wave that actually raises the temprature of the weld to welding temperature.

3. The machines, being high power factor devices, are resistance conscious. Therefore, more care must be taken in concentrating resistance in the work.

4. In welding of thin aluminum, it requires more secondary current than a-c welding. The nugget can grow faster than the energy can be placed in the joint.

Figure 22 shows some typical wave shapes produced by these various types of welding machines.

Summary

The final selection of welding equipment must have the following considerations:

1. The ability of the equipment to weld the specified material.

2. The cost of the equipment.

3. The voltage regulation imposed on the supply system by various types of machines.

4. The cost of reinforcement of the present supply system versus the cost of the machines and their correction devices.

5. The total of machines involved and their diversity factor.

6. The rate of production of one system versus another keeping in mind the limitations of each system and the number of machines involved.

The a-c single-phase machine is generally found the most economical if the power supply is adequate, if not, a complete study must be made of the total installation and the power system before recommendation of any certain type of machine and its correction device versus power-system reinforcement.

Discussion

C. N. Clark (Duquesne Light Company, Pittsburgh, Pa.): When determining the proper type of power supply for various types of resistance welders, utility engineers often encounter certain limitations which would not apply if service were to be provided instead to an equivalent steady 3-phase load. With the wide variation of conditions at various locations on a power system, individual study of each welder load is necessary in order to provide the most economical service, and at the same time make possible the satisfactory operation of the welder without disturbing service to the many thousands of light and power customers in the same general neighborhood.

It is noted that the author divides voltage fluctuations with accompanying lamp flicker into two classes:

1. Noncyclic, slower than once per second with a 2.0-volt tolerance.

2. Cyclic, faster than one and one-half times per second with tolerances as low as 0.5-volt in 115-volt terms.

Our experience, based upon a large number of observations by several independent groups, indicates that the border line of irritation follows a rather smooth curve with no sudden break at any particular frequency. The curves most frequently used by utility companies show a permissible 2.0-volt fluctuation at a frequency around one per minute, decreasing gradually to values of 0.4 to 0.5 volt at a frequency of approximately 6 per second. These values are considerably under those shown by the author in the curve of Figure 2.

The use of series and shunt capacitors for power factor correction and reduction if instantaneous demands for resistance welders should be encouraged, since in many cases the additional cost for power factor correction is much less than the extra investment necessary to reinforce the power system and reduce the voltage fluctuations which would otherwise result from the use of an uncorrected welder capable of welding the same material.

The installation of a Scott connected bank to serve the welder would result in a sizeable reduction in voltage fluctuations caused by single-phase a-c welding loads. Its limited use by utilities is probably due to the need for special transformer taps. Many utilities use instead a 3-phase bank with a delta connected secondary, or a single transformer with a 4,000-volt primary winding when supplying a welder from a 2,300/4,000-volt 4-wire 3-phase system. The regulation of the primary circuit by either of these methods may be from $33^1/_3$ to $66^2/_3$ per cent less than the regulation obtained by serving the same welding load from a single phase 2,300-volt transformer connected between the phase wire and neutral.

This variation depends upon the relative values of impedances for the substation equipment and the conductors of the primary circuit for each location. The voltage regulation due to the use of various types of resistance welders is also affected by the X-R ratios of the power system and the X-R ratio of the welder.

On a 2,300/4,000-volt 4-wire 3-phase system, a balanced 3-phase load would cause one-sixth as much voltage regulation in the primary circuit conductors as an equivalent single-phase load supplied from a 2,300-volt single-phase transformer connected to the phase wire and neutral of the same circuit. This ratio offers a tremendous advantage for any balanced 3-phase welding load, provided an accompanying cyclic flicker can be avoided.

The description of the characteristics and basic circuits for the various types of 3-phase welders should be very useful to utility engineers, and should help them in their work of providing adequate welder service at a minimum cost. The consideration given by the author to the effect of welder operations on the power supply system is greatly appreciated, as too much emphasis cannot be placed on this phase of the problem.

E. M. Callender (The Budd Company, Philadelphia, Pa.): This paper is a résumé of many types of resistance welding equipment applicable to the widely varying power supply conditions encountered in factories and locations employing the process. The author is to be congratulated on grouping these various types of equipment and for enlarging upon their characteristics. The paper covers in modest detail the power supply problem. It also deals more specifically with the required connection of each type machine.

Consideration is hereby given in connection with the introductory statement concerning the use of single phase a-c welding machines whose supply is taken around a 3-phase system. Loading a group of single-phase welders fairly evenly around a 3-phase plant feeder may achieve:

1. Economy in a long bus feeder.
2. An improvement in the regulation of supply feeder and hence improvement in weld consistency.
3. More effective use of existing maximum available supply of kilovolt-amperes.

This is in comparison with use of single-phase feed on the same application. It is likewise verified in the paper by comparative regulation values under regulation of single-phase machines on 3-phase lines. Incidentally, it is feasible to install low reactance balanced or fairly balanced 3-phase feeders. It must be remembered that in large plants the concentration and growth of welding machines is not like that of an urban community—something very permanent—but the installations may shift over a large area through change in production methods and by change in the type work.

It is difficult to judge from technical papers the relative extent of various welding problems on power supply. Even so, every installation study will naturally divide itself into two parts.

1. Power company supply line that must satisfy both utility and customer to the extent of the compromise necessary.
2. Adequate plant distribution feed and welding equipment to handle the maximum capacity of resistance welding with recommended regulation that will provide consistent welding conditions under diversity loads.

Obviously, in power scarce areas the choice of (2) must be made with such power demand economy that (1) can be satisfied based on the economics involved. By the same token the customer may not be allowed to obtain increased weld loads from the power company at a later date. There is a three man team of utility, equipment manufacturer, and customer who must work closely together for the coherence of a well co-ordinated installation. Yet, much of the responsibility falls on the shoulders of the welding engineer and his company for proper selection of equipment.

In an art that dates far back most of the advances in resistance welding have been made in slightly over a decade through the introduction of electronic tubes. Early processes were modernized and many new equipment developments occurred through the advent of this precision power controlling device. Since then many fine technical contributions have been made covering advances and solutions to more numerous problems.

The welding engineer may find insufficiency in technical papers taken individually, since they may not provide the exact information required. He really has a need for engineering texts on the subject. Collectively, these welding papers have greater value, and the AIEE electric welding committee has possibly advanced the cause by compiling a bibliography covering major technical papers in various journals on equipment and power supplies written since 1939. This will be available in the near future.

There is a challenge for the introduction of engineering texts on the subject of power supply problems and equipments. Such books would have to be authoritative, very complete, and should contain a wealth of customer experience. Technical papers could form a nucleus for subject matter in some cases.

The author's summary concluded that the a-c single-phase machine is generally most economical where power supply is adequate. The writer wonders if any advantage might be taken by low production users having groups of two to five a-c single-phase welders (on a phase) in certain critical utility power line cases of small users wherein all units are relay interlocked to take their turn on the power line singly. Each call for a weld is memorized on the control board which places it in proper turn and provides the relay "go ahead" when preceding machine welds are completed. This scheme limits the line demand to single machine loads. With present-day high-speed relaying the method could be modernized to reduce the welder delay to an inconsequential minimum.

Whatever equipment is chosen in an application, it should retain flexibility as a keynote to its lifetime usage. Choice of welding equipment, aside from the load demand, ought to have as a consideration its general utility on future jobs that may vary considerably from the initial application.

Finally, one unnecessary line overload can be prevented with a-c electronic heat controlled welders by maintaining the welding transformer voltage tap so that small no-current gaps between waves will occur for any heavy welding setup. Large electrical phase back angles on heavy loads will increase the peak line current by as much as 25 to 50 per cent and add that much increased regulation problem.

W. K. Boice (General Electric Company Schenectady, N. Y.): The paper emphasized the desirability of a resistance welding load which is 3-phase and is balanced. The most important reason for desiring balance is that the drop in rms voltage, on a given 3-phase system, caused by a balanced load is essentially half that for a single-phase load of the same kilovolt-amperes and power factor. The other reasons listed in the paper are, we believe, seldom of comparable importance.

The paper points out that metallic rectifier welders have less harmonic content in the current wave than some frequency converter welders. It implies that converter welder loads are consequently less perfectly balanced. However, the degree of unbalance is independent of the percentage of harmonics in the input current wave, because the harmonics are essentially the same for all phases.[3]

The degree of unbalance is practically negligible for either a metallic rectifier welder, or a frequency converter welder.[1]

The voltage drop for either type of welder may be estimated with reasonable accuracy by neglecting harmonics, and by assuming the load to be perfectly balanced.[1]

When harmonics are neglected, the input current is a sine wave which lags somewhat behind the voltage wave. The angle of lag is caused principally by the presence of leakage reactance between transformer windings used for rectification or conversion. It may be determined by the welder designer by methods[2] employed in power rectifier practice, and should be considered in estimating voltage drops.

Principles and Practices of Relaying in the United States

E. L. HARDER
MEMBER AIEE

W. E. MARTER
ASSOCIATE AIEE

Synopsis: The rapid growth in power system size and interconnection over the past 30 years has greatly increased the problem of isolating faults. Standards of service have increased, making necessary greater reliability, and higher speed of operation. Innumerable relaying devices and schemes have been developed to meet the more exacting requirements. Some have been designed for special situations and others apply to basic situations which occur on many systems. It is these latter which it is hoped to discuss in this paper.

THE AIEE through its relay committee has encouraged these developments through the dissemination of information in hundreds of technical papers, conferences and committee reports.* The relay committee maintains an up-to-date bibliography of these papers and reports, as well as of other published articles and books. The 1944 to 1946 section was issued in November, 1947.[1] We shall draw freely on the fundamental data contained in the reports and papers of the relay committee.

General Philosophy of Relaying

The system is divided into protective zones as shown in Figure 1, each having its protective relays for determining the existence of a fault in that zone and having circuit breakers for disconnecting that zone from the system. It is desirable to restrict the amount of system disconnected by a given fault; as for example to a single transformer, line section, machine, or bus section. However, economic considerations frequently limit the number of circuit breakers to those required for normal operation and some compromises result in the relay protection.

The relays operate usually from currents and voltages derived from current and potential transformers or potential devices. A station battery usually provides the circuit breaker trip current. Successful clearing depends on the condition of the battery, the continuity of the wiring and trip coil, and the proper mechanical and electrical operation of the circuit breaker as well as the closing of the relay trip contacts.

In event of failure of one of these elements, so that the fault in a given zone is not cleared by the first line of defense, relays and circuit breakers, some form of back-up protection is ordinarily provided to do the next best thing. This means, first of all, to clear the fault automatically, if at all possible, even though this requires disconnection of a considerable portion of the system. Once cleared, the system can generally be rather quickly restored, whereas if the fault hangs on, the line may be burned down, or apparatus damaged beyond repair, or the entire system may be shut down for an extended period. The measures taken to provide back-up protection vary widely depending on the value and importance of the installation and the consequence of failure. These will be discussed in a separate section.

Some utilities in measuring the performance of transmission line relay protection analyze all relay trip operations as shown in Table I. The numbers shown are typical of a system operating 3,000 miles of 110-kv line.

This is only an analysis of faults for which the relay tripped or should have tripped. For each of these there were several cases where the relays should not have tripped, and did not. Thus the total number of discriminations made by the relays is possibly five to ten times as great as the trippings. The percentage failures are correspondingly less on this larger basis.

However, Table I has been presented at this point to bring out the following factors that enter into a highly successful protective relay system:

1. Good equipment, relays and instrument transformers.
2. A system design that can be protected and correct application of relays to provide the possible protection.
3. Good maintenance primarily to assure that all the accessories are operative.

The correct but undesired trippings are cases where the relays have done what should be expected from their characteristic curves and settings and the fault conditions involved. There may have been system changes since their application, or incorrect initial application, or application with foreknowledge that certain conditions would unavoidably operate the relays, but this was necessary to secure tripping in other desired cases.

It is important to bear in mind that simple standard system design plans can be better protected. Distance measuring and carrier or pilot-wire types of relaying are much less subject to disqualification by system changes than are over current types.

Wrong tripping and tripping failures, together with all causes of failure to clear faults, have been broken down further in AIEE conference reports and found to stem largely from human errors, such as leaving the trip circuit open after test, or to open circuited trip coils, or mechanical failure of the circuit breaker, and blown fuses in trip circuits (if used). Only a small part of the total failures occur in the protective relay itself. Thus close

Figure 1. Typical system showing protective zones

attention to the initial design, installation, testing, and maintenance of all of the accessory equipment as well as of the protective relay proper are needed to assure successful operation.

The application of protective relays properly requires evaluation of several factors, namely:

1. The requirements of the power service and desired functioning of the system during fault conditions to produce this result.
2. The currents, voltages, temperatures, pressures, or other indicators at time of fault which provide the fundamental basis of discrimination.
3. The characteristics of available or standard relay elements.
4. The schemes in which they are used.

A wide variety of characteristics are now available operating in response to the prime quantities themselves, or to various functions of these prime quantities, such as power, phase angle, power factor, current comparison, power comparison, impedance, reactance, modified reactance, current ratio, or phase-sequence component.

In each case the response may be instantaneous, meaning no intentional delay, or the operation may depend in a predetermined manner on the electrical quantities, and time of duration.

Basic Elements

By taking some liberties with exactness and making no pretense of completeness, we can list here for reference, the more commonly used relay characteristics and their underlying principles of operation. The schemes in which the elements are used are much more numerous. The more common ones will be described under the application headings, such as generators, transformers, and busses.

Instantaneous Elements

Principles of a number of the more commonly used relay elements are shown in Figure 2. For instantaneous response to current or voltage the solenoid element, (*a*), is most common, appearing individually or as the instantaneous attachment with the induction-type overcurrent relay. The beam element, (*b*), with spring or weight bias is used where low burden is desirable, as when setting for low ground currents with low-ratio bushing current transformers. The polar element, (*j*), is of far lower burden than the nonpolar types and has come into widespread use since 1935 as the receiver relay of directional-comparison carrier equipments, and the basic element when supplied from networks or electronic devices. For example, it appears as the operating element in a pilot wire relay, in a phase-comparison carrier relay, in linear-coupler bus protection, and in supervision of pilot wires.

Because of its higher pick-up to drop-out ratio and less accurate setting the clapper-type element, (*c*), is used less frequently for the primary protective functions but is widely used as an auxiliary relay.

Induction Elements

The induction-disk element, (*d*), continues to be most widely used, its reliability and inherent time characteristic giving it great flexibility for co-ordinating relays in series or co-ordinating with fuses or direct-trip devices. A variety of characteristics are available from the definite-minimum-time, which is ideal for securing definite time steps between relays, to the very inverse which provides faster tripping with the same margins when the fault current drops considerably from one relay location to the next. The more inverse characteristic also co-ordinates better with fuses.

The induction disk serves as a directional element, (*e*), or, when used with a spring, as a watt element, (*l*), the electric torque being proportional to $EI \cos \theta$, where θ is the power-factor angle. Either of these can, of course, be current polarized instead of voltage polarized for use in ground relaying when a bank-neutral current is available.

The relative phase of voltage and current can be shifted by internal or external phase-shifting devices to produce maximum torque for power factors other than unity, as in (*g*). For example, the directional element for ground relaying usually has its maximum torque for current lagging the voltage by 60 or 70 degrees to provide maximum torques for the fault conditions. A pure watt characteristic is used with the 30 and 60 degrees connections for phase directional relays, the phase shift being provided by using the voltage of a different phase from the current. With the 90 degree connection this shift is too much and the voltage is advanced about 45 degrees by a phase shifter to provide a maximum-torque position for a current 45 degrees lagging.

The disk is provided also with an electromagnet, (*o*), producing ratio characteristics for use as a differential relay for generators or transformers. The generator-differential relay is shown in (*o*) the transformer relay having windings 1 and 2 tapped for different current-transformer ratios.

Referring to Figure 2 (*o*) the differential current produces lower-pole flux which acts in the operating direction on disk currents produced by the upper pole which is transformer fed from the same differential current. The restraint torque giving the ratio-differential characteristic, is produced by the through current in coils 2–3, which supply disk current by transformer feed to the upper pole, and by lower-pole flux produced by the same through current.

The induction disk provides a tripping-

time-proportional-to-impedance characteristic as shown in Figure 2(*s*).

Multiple Electromagnets or Disks

Two electromagnets on the disk provide for balancing mechanical torques with no phase angle effects (see (*p*)). When these are both current electromagnets, the relay is the regulating-transformer differential relay which balances the current in the shunt exciting winding against the through line current. For example in a ±10 per cent regulating transformer, it operates when the shunt current exceeds about 15 per cent of the through current. When both electromagnets are voltage energized, the voltage-differential relay results. When one is voltage (actually responsive to KE^2) and one is a product element, $EI \cos (\theta-\phi)$, a balance occurs when $I \cos (\theta-\phi) = KE$. This impedance characteristic is shown in current and also in an R-X plot in (*m*).

A second disk on the same shaft provides space for two more electromagnets. This structure is used as the phase-balance relay for motor protection, whose characteristics are shown in (*p*). It is used for the 3-winding-transformer differential relay, using one operating electromagnet and three restraint electromagnets, (*n*). With two current-input windings on each electromagnet, and using two relays per phase the multirestraint bus differential relay results. Its use will be described later.

Multiple-Pole Cylinder or Disk Elements

The multiple-pole cylinder or disk element is illustrated in (*f*). The example shows how it would be energized to act as a single-phase directional element having torque proportional to $EI \cos \theta$. This element also serves as a polyphase-directional element by the connection, (*g*).[32] The multiplepole element is flexible making possible a variety of other combinations.

4-Pole Induction-Cylinder Elements

These high-speed elements serve a variety of purposes as shown in Figure 2(*u*), (*v*), (*w*), and (*x*). The element (*u*), designated a mho element[24] operates with torque $E^2 \cos (\theta-\phi)$ restrained by torque proportional to E^2. It produces the circular-impedance-tripping locus passing through the origin or relay location, the same as shown for the induction disk in (*m*). Or with either element, the circle

can be shifted from this position by current compensation, IZ_0, in the restraining circuit, as indicated. A directional-starting unit, (*p*), is obtained using current times shifted-quadrature voltage for operating and the product of two delta voltages for restraint. This results in maximum torque for current 30 degrees ahead of the quadrature voltage or about 60 degrees lagging the unity-power-factor position.

The special impedance characteristic, (*w*), obtained by I^2 operating against $EI \cos(\theta+20$ degrees) is used to restrict the tripping area to assist other relays in differentiating heavy load swings from faults. A reactance element, (*x*), is obtained similarly with the phase-shift devices arranged so that the maximum-torque line is along the (*x*) (reactance) axis.

Inductor-Loop Element

The inductor loop, (*h*), provides a very high speed and very reliable directional element which has been used for many years now in high-speed distance measuring relays.

Balance-Beam Element

The basic balance-beam impedance element is shown in (*i*), a balance occurring for $E/I = Z_0$. For higher impedances than Z_0 (current relatively lower) the contacts remain open, whereas for lower impedances (relatively higher currents) they close quickly. Since the balance is mechanical, the phase angle between voltage and current is of minor consequence and the tripping characteristic, plotted on an R and X diagram is substantially a circle.

Modified-Impedance Characteristic

The circular characteristic may be shifted by some circuits auxiliary to the element as shown in (*k*), in order to provide better discrimination between fault currents and load and swing currents on long, heavily-loaded transmission lines. The shifting imparts a directional characteristic to the relay in addition to narrowing its tripping region to more nearly just that required for faults.

Networks and Auxiliary Circuits

It may be noted that in discussing fundamental relay elements certain auxiliary circuits, external to the mechanical relay have been introduced; in (*g*), the phase shifter; in (*j*), the Rectox; and in (*k*), a full fledged network to produce in the relay element proper, the desired currents. This is a trend of which we shall certainly see more as time goes on, as static circuits are devised to produce a simple current output proportional to the desired function of the various line currents and voltages.

Sequence-Segregating Networks, I_1+KI_0

The method of symmetrical components has been the key that has unlocked the door to a number of the aforementioned possibilities, some of which are illustrated in (*r*), (*s*), and (*t*). The positive- and zero-sequence network in (*r*), is commonly used in pilot-wire relaying, where it is desired to compare over the wires only one quantity, which is a good measure of the fault current irrespective of what kind of fault it may be, that is *A-B*, *A-Grd*, *ABC*. The relay can be given almost independent and widely different settings for phase faults and ground faults, using the single relay element. For example, it may be set for one ampere of ground fault to provide the requisite sensitivity, but for ten amperes of 3-phase current to avoid operation on loads.

A negative-sequence directional element is shown in (*s*). It is an adequate directional element for ground faults on reasonably well-grounded systems, and requires only two potential transformers rather than three as with usual residual-directional relays.

Another novel application, (*t*), is the phase-selector relay to determine which phase is faulted. This information is necessary in single-pole tripping and reclosing schemes. It is predicated on the knowledge, from symmetrical-components theory, that the negative-sequence current in the faulted phase only is in phase with the zero-sequence current. Individual overcurrent elements in the three phases could not be used for this selection as all three would pick up for a single line-to-ground fault on many solidly-grounded systems.

Alternating Current Generator Protection

Most a-c generators above 1,000 kva and many smaller machines are equipped with differential protection arranged to trip if the currents at two ends of each phase winding differ. This scheme is shown in Figure 3. Smaller machines are sometimes operated without differential protection, but if paralleled with larger machines or with a system, they are frequently arranged to trip off on a reversed flow of power into the machine for a short time interval.

For differential protection the normal-speed, induction, ratio-type relays are used in the large majority of cases, their speed (about 0.1 second relay time on severe faults) being adequate to prevent serious burning of the iron in nearly all cases. However, high-speed generator-differential relays are available providing 1-cycle protection, and are being used with 100 per cent success in an increasing number of important applications.

If the generator is solidly grounded, or grounded through a reactor or resistor, drawing at least full-load current for a ground fault at a line terminal, the usual 10 per cent differential relay operates for practically any short circuit within the machine and for grounds to within 10 per cent of the neutral, or closer if the ground current is higher.

The relay is usually arranged to trip the generator, field circuit, and neutral circuit breakers (if any) simultaneously by a manually-reset lockout relay in new installations. Frequently the relay also trips the throttle and admits CO_2 for fire prevention.

Generators feeding directly into step-up transformers are now frequently being equipped with some form of very high-resistance grounding, which draws only a few amperes of current during a ground fault. Such a scheme is shown in Figure 4, using distribution transformers with secondary resistors. The current being too small to operate the differential relay, a separate voltage relay, R, (or a current relay in series with the resistor) is used to trip the unit for ground fault. In a few cases this is being used for alarm rather than tripping, where the consequence of loss of the unit is so severe as to warrant operating with a ground until the load can be reduced or shifted elsewhere.

Field Protection

While a large number of machines still operate without any protective relays to function on loss of field, there is a trend to more general use of equipment for this purpose. On some systems where loss of field would cause serious low voltage and danger of instability, but where the system is operated in a way which can tolerate the loss of one machine, automatic means are being provided to disconnect the machines on loss or partial loss of field.

Fairly common is the use of a d-c undervoltage relay, a d'Arsonval relay in series with a resistor, connected across the slip rings for field short circuit detection; also a similar element across the field ammeter shunt for undercurrent or open field detection. These do not provide complete protection and there are a number of installations of reactive power relays used at the generator terminals in conjunction

with under voltage to trip for any field reduction which would cause serious low voltage.

On many closely knit metropolitan systems loss of field has been found to be not serious if immediately corrected. The operator attempts to restore the field, the generator in the meantime operating at somewhat reduced load as an induction generator. If he cannot restore field within a few minutes he must trip the line circuit breaker to avoid injurious rotor heating.

Field Ground Detection

Some form of field ground detection is frequently provided. It is considered most important to detect the first ground because a second could short circuit part of the field winding causing unbalance and vibration which could wreck the machine. Schemes used are illustrated in Figure 5. The a-c scheme provides complete coverage for solid grounds. The d-c scheme gives nearly complete coverage, complete if the main field rheostat is varied. In some instances vibration detectors[9] are used if the machine is known to be operating with a ground on its field. This will trip the unit instantly in event a second ground occurs. The over-all protection scheme frequently includes armature and bearing temperature indication and sometimes alarms. Less frequently field temperature indications are provided. The voltage regulators are sometimes equipped with over- and under-voltage protection and, of course, over-speed protection is provided.

Transformer Protection

As shown in Figure 6, differential protection continues to be the principal form of relay protection used in the United States for transformers of 1,000 kva and above. The normal-speed induction relays generally used are of the ratio type, having minimum-trip values of 2.5 to 3.5 amperes in secondary terms and increasing with load due to the 25 to 50 per cent ratio characteristic to reach 4 to 5 amperes at the full load point. If the current transformers are applied with 4 amperes corresponding to full load, this results in an average sensitivity of three-quarters to full load. The desirability of improving the sensitivity is generally recognized.

It is well known that the exciting current of a transformer appears as differential current, the same as does fault current, and that the inrush-exciting current, when the transformer is energized may reach a value of several times full-load current for a number of cycles. Occasional false trippings due to inrush current are encountered even with the relatively coarse sensitivities cited before. This problem is more severe when the system is very stiff relative to the transformer, that is, when the ratio of available short circuit kilovolt-amperes on the bus to the kilovolt-ampere of transformer energized is large. Magnetizing-inrush tripping suppressors are used in some cases where false tripping would otherwise be encountered.

Inrush-Tripping Suppression

One form of suppressor is shown in Figure 7. The relay is temporarily desensitized for a time interval sufficient for the inrush current to have largely died out. When the transformer is energized, voltage relays on each phase pick up and set up the high-speed trip circuit after a few seconds interval, T_2, which is long enough for the inrush current to have subsided. If a severe fault occurred during this desensitized interval, one or more of the voltage relays would remain open; the differential relays would operate, closing T_1; and tripping would occur through T_1 and the voltage-relay back contacts. An inrush, with no fault, would not drop the voltage below the settings of the voltage relays and would not trip.

A severe inrush may occur due to skipping an odd number of half cycles of voltage application to a transformer while a nearby fault is on the system then cleared. The timer, T_2, resets during this period providing the desensitizing needed to take care of the subsequent inrush.

A harmonic-restrained relay is used also to secure increased sensitivity and greater freedom from tripping on inrush. This relay takes advantage of the greater proportion of harmonic currents found in the inrush current as compared with fault current.

Differential relays of the high-speed type continue to find use where required to co-ordinate with other high-speed elements, and in other important applications. However, these constitute a small proportion of all new applications, the large majority using the normal-speed induction-type relay. In the high-speed relay the tripping suppressor is definitely required and is built in with the relay.

Gas-Pressure and Gas-Accumulator Relays

Increased attention is being given to gas-pressure and gas-accumulator relays because of their popularity in Canada and elsewhere. Some of both are being used in the United States, although at the time of the 1946 survey they were still very rare.

The gas-pressure relay, which is used for tripping, operating either on pressure or on rate of pressure increase, is claimed to offer advantages in sensitivity although this has not been proved definitely.

The gas-accumulator relay, which is used for alarm only, and only on transformers completely filled with oil, has been proved definitely very sensitive and very useful in Canada. Gas-accumulator relays are not in use on transformers having a gas cushion above the oil.

Three-Winding Transformers

For 3-winding-transformer protection, an induction-type relay having three restraining coils is generally used, and is connected as shown in Figure 8(*a*).

Regulating Transformers

Regulating transformers for voltage and phase-angle control constitute a special problem because of the change in ratio taps during operation. Figure 8(*b*) illustrates the most modern differential relay protection for such a unit. An element of the Figure 2(*p*) type (one disk, two electromagnets) is arranged to trip if the current in the shunt-exciting winding of the regulator greatly exceeds the proper proportion of the series-line current. For example with a ±10 per cent voltage regulator, a typical relay might be set to operate for any current in the shunt winding greater than 15 per cent of the line current. This provides sensitive protection for the shunt transformer. In addition normal 2-winding transformer-differential protection is applied around the entire unit, providing overlapping protection with the bus and line protection and guarding the series transformer. It is difficult to provide complete protection to the series transformer and tapped regulating windings. Optimum use is made of ground protection, for example as shown in Figure 8(*b*). However, the possibilities of this protection vary with the arrangement of windings and whether grounded or not.

Gas-accumulator and gas-pressure relays may provide the desired sensitivity for this application. However, as mentioned, the gas-accumulator as at present developed is not applicable to transformers having an inert gas cushion. The separate compartments for transformer and tap-changer would require separate elements. The sensitivity of a practical pressure element may well be greater than electrical relay protection. However, this has not been demonstrated as yet.

Co-ordination with Thermal Relays

An increasing number of transformers are supplied with thermal devices for alarm and protection under load conditions. There is a move in the United States to provide a definite co-ordination so that these will not operate faster than protective relays, during fault conditions. Selective tripping can then be secured on feeders on the secondary side of the transformers. The co-ordination figures have not been set but it appears they may be of the order of 30 or 40 seconds at 5 times normal and 5 seconds at 20 times normal. All thermal relays would operate slower than these values and all protective relays faster.

Remote Trip for Transformer Faults

Because of the high record of reliability of large power transformers, a circuit breaker between the high-voltage side of the transformer and the line frequently cannot be justified, purely for protection of the transformer, and the transformer is very little hazard to the line. However, an intermediate measure costing much less than the high-voltage circuit breaker is frequently provided to trip the remote circuit breaker (or breakers) necessary to clear in the event of a transformer fault. The transformer differential relay is sometimes used to initiate a remote trip signal over a carrier or pilot wire channel, particularly if the channel is already available for some other purpose. Another method is to close a fast spring-operated high-voltage grounding switch in response to the relay indication. This trips the ground relays at the other terminals of the line, at the expense of some added shock to the system.

Bus Protection

The advantages of bus protection in clearing faults rapidly from a system are well recognized by the industry and the provision of relay protection for major station busses has been standard practice for a number of years. The problems involved in such protection are also quite well known. One of the principal problems is the saturation of current transformers by the d-c transient component of the short-circuit current as in Figure 9. In severe cases the d-c transient component may require 100 times as much flux capacity in the transformer as is required by the a-c component to completely prevent saturation. The theory of this problem was presented before the Institute[19] in 1929.

Figure 3. Generator-differential protection-connections for one phase using the percentage-differential relay for generator protection

There have been a number of successful solutions to this problem, as well as the fault-bus scheme,[12] which completely avoids it. First was the use of large current transformers which would not be saturated by the d-c component. These were used in the simple differential scheme Figure 10(*a*), with low-resistance leads to minimize the current transformer requirements. A formula was advanced specifying the requirement of iron cross section, turns and lead resistance for nonsaturation.[25] It is:

$$\frac{E_s}{R}=4.44\,IT$$

where T is the short circuit current d-c time constant in cycles. I_s is the a-c exciting current in the secondary, selected as the threshold of saturation. It would be taken as less than the relay setting by a suitable factor of safety.

E_s is the required secondary rms, a-c voltage corresponding to I_s on the a-c saturation curve of the current transformer. This determines the needed iron cross section and turns, or the iron if turns are fixed.

I is the crest value of symmetrical subtransient current, secondary amperes.

R is the secondary circuit resistance in ohms, including the transformer winding and leads up to the relay (or point at which all current transformers are paralleled.)

The a-c flux is neglected. It is usually relatively small as the ratio of maximum d-c flux to a-c flux is $2\pi T$ or 37.7 for a 6-cycle d-c time constant.

For $R=0.5$ ohm, $I=100$ amperes, $T=6$ cycles, and taking I_s as one ampere, in considering a 5-ampere relay setting; E_s becomes 1,332 volts. A current transformer which would generate this voltage at 1.0 ampere exciting current is very large. Thus, this was a bull-by-the-horns solution and the size, weight, and cost could be afforded only in the most important installations. However, it did provide the possibility of instantaneous tripping without any time delay.

A method[15] has been developed for calculating with reasonable engineering accuracy, the time-to-saturate with offset currents, and the time and current settings required to prevent misoperation with time-delay overcurrent relays and usual current transformers.

Induction Type Overcurrent Relays

On busses of moderate time constant say 0.1 second or less, and with somewhat better than average current transformers, satisfactory protection can be obtained with a straight differential scheme, Figure 10(*a*), using the fast induction element of Figure 1. A small ratio of maximum to minimum fault is favorable to this application. Relaying times of the order of 3 or 4 cycles for maximum faults and up to 8 or 12 cycles on minimum faults can be obtained in some cases. As mentioned, the performance can be predicated.[16] However, the time delays involved in less favorable cases are frequently so long as to point the need of a better solution.

Even on substation busses having a d-c time constant as short as 0.01 second false tripping has been experienced with 300/5 bushing current transformers and standard induction relays in the connection of Figure 10*a*, with 4 *A*. tap, 0.5 time lever, giving 0.15 second time at 10 times tap, and with a fault current of 13,000 amperes. While this has been overcome by changing to 1,200/5 current transformers, nevertheless present practice would be to install ratio-differential relays in these cases, providing both greater sensitivity and greater safety factor.

Multirestraint Ratio Differential Relays

Relays[20] have been developed which will not operate falsely even when used with normal sized current transformers which saturate due to the d-c component of current. These are multirestraint relays, connected as in Figure 11; however, their success is due also to exploitation of variable percentage characteristics, and the tendency of the d-c component to brake, rather than drive, the induction disk.

No small part of this development is the reduction of the operating limits to a few simple rules which insure safe application. This relay scheme provides operation generally in from three to six cycles and can be set as low as one per cent of the maximum through-fault current.

Linear Coupler Scheme

The multirestraint relays just described may, of course, be used when the setting does not need to be as low as one per cent of the maximum-through-fault current. However, on busses where a setting of six per cent or more of the maximum through-fault provides the requisite sensitivity a simpler and faster scheme (one cycle) can be used known as linear-coupler bus protection.[11,12] The linear coupler is an air-core mutual inductance used directly in the primary circuit in the same manner as a current transformer except that the secondaries are usually connected in series, as shown in Figure 10(*b*), instead of in parallel as are current transformers, Figure 10(*a*).

The secondary induced voltages are proportional to the primary currents, a ratio of five volts per 1,000 amperes being commonly used. These voltages, which add up to zero for through faults, and to a value proportional to the fault current for internal faults, are joined in a series loop to the relay as shown in Figure 10(*b*). The ±1.5 per cent tolerance within which the mutual inductances are held commercially, limits the maximum possible false differential to 3 per cent. Thus the minimum setting of 6 per cent allows a 2:1 factor of safety. Solenoid elements Figure 2(*a*) are used for settings down to about 1,500 amperes on a 6-circuit bus, and polar elements Figure 2(*j*) with saturating transformer and Rectox for lower settings.

Impedance Schemes

Busses having reactors in a majority of the feeders and possibly in the bus-tie circuits provide the possibility of protection by impedance relays.[13] Impedance or modified-impedance elements can be used, see Figure 2, (*i*) and (*k*). For a fault on the bus, the maximum impedance measured is that of the arc which is taken as about 300 to 500 volts per foot for current above 500 amperes. Considering the possible arc length during the first few cycles of fault, a maximum arc voltage can be computed and this, divided by the minimum fault current gives the greatest fault impedance encountered for internal faults, that is, for faults on the protected bus. Provided this impedance is smaller than the impedance from the relay to a fault anywhere beyond the reactors, a basis of discrimination exists and the impedance scheme can be used.

Figure 5. Field-ground detector schemes

R = resistance in ohms of potentiometer resistors
R_m = resistance of relay plus fault resistance, in ohms
X, Y = resistances in ohms to point of fault from each end, including the field rheostat if used

(b) *Alternating Current Scheme*
If the bearings used do not result in a definitely and permanently grounded rotor, then a sliding contact should be connected between the shaft and ground to provide such definite grounding

Two relay arrangements have been used. When the bus tie circuits include reactors, separate impedance relays can be used on each generator or transformer feed to the bus, operation of any of which will trip the bus. This arrangement is most feasible when the generators and transformers are matched, acting as a unit, and the generators on the bus are either high and low pressure units of a single combination or are treated as a single generator. The other arrangement requires totalizing all of the main feeds to the bus and the use of a single set of impedance relays. The grouped main sources provide the possibility of a large false differential current for through faults on one of these main circuits. The voltage is also low under this condition if the source circuits are not equipped with reactors. Usually a fast induction relay, Figure 2(*d*), is used together with adequate current transformers in the main feeds so that it will not operate for through faults on those feeders. Combined impedance and fast-induction-element operation is then required to trip the bus.

Directional relays can be used in a variety of ways, either as the basic protection, tripping when fault current flows into and not out of the bus,[17] or as an adjunct for determining which of several bus sections included within a common differential protective zone is in trouble.[11]

Fault Bus

For new and certain existing segregated phase busses, the fault-bus scheme[13,14] provides a distinctly different mode of attack to the bus protection problem. All metal parts to which the bus may flash are connected together and grounded through a current transformer and relay. This construction lends itself particularly well to metal-clad switchgear. The entire cubicle or switchhouse is insulated from ground except for the connection to ground through the current

Figure 4 (left). Relay scheme for light-resistance grounding used with unit system

Figure 6. Transformer protection survey[13]

transformer. The simplicity of this scheme is strongly in its favor where the construction permits its use. However, it is sometimes difficult to secure overlapping protection with the adjacent system elements.

Summary of Bus Protection

While personal preference, experience, and factors peculiar to a particular installation play a large part, some of the general factors that lead to the selection of one or the other of the several schemes are described below. One-cycle operation, simplicity, and savings in cable costs, as compared with the multirestraint scheme, are favorable to linear couplers.

Quite adequate speed (3–6 cycles), the use of existing current transformers, the use of current transformers which can be used for certain other purposes also (such as back-up protection), simple application rules, and ability to set for minimum faults one per cent of maximum-through-fault, sometimes eliminating need of separate ground relay, are all favorable to the multirestraint system.

Existence of reactors and the cost or difficulty which would otherwise be involved of installing current transformers on all feeders, favors impedance schemes.

The fault-bus scheme is limited to cases where the structure can be insulated from ground, but in these cases its simplicity is favorable. Simple time delay over current frequently involves excessive delay but if used with ordinary current transformers, it may be lowest in cost.

Figure 7. Inrush trip suppressor

D_1, D_2, D_3 = High speed differential relay contacts

V_1, V_2, V_3 = Voltage relays and corresponding contacts

T_1, T_2 = Timers, fraction of cycle and few seconds respectively

S = Seal in

The directional schemes are used to good advantage by some and have the advantage of securing fast operation with ordinary current transformers, but are considered less favorably by others because of the number of contacts to be coordinated for correct operation.

In most cases, spring-operated, manually-reset auxiliary tripping relays are used, unlatched electrically by the main differential relays. These trip the necessary circuit breakers and provide lockout.

Line Protection

By far, the most notable change in line protection in the last ten years has been the remarkable increase in pilot protection, both pilot-wire and carrier. A number of complete systems of high-voltage lines have been almost completely carrier equipped and a great many companies have programs leading to eventual provision of carrier on nearly all important lines, 66 kv and above, and on many lines below this voltage. Pilot-wire protection is used on short sections of high-voltage lines and extensively on the lower voltage, 13.2- to 33-kv lines, particularly in metropolitan areas. There have been impressive advances in this field including new and improved carrier[25–28] and pilot-wire[29,34] relay schemes, developments in the science and knowledge of pilot-wire protection against induced voltages[31,32] and rise in station ground potentials. There is much greater confidence and knowledge in the use of power-line carrier.

Protection of a Typical System

A composite diagram showing many of the line-protection situations which arise in power systems is given in Figure 12. The main transmission lines are shown as 220 kv, although they might be from 66 to 287 kv, or higher, bringing in power from a remote hydro-plant or interconnecting with an adjacent system. These lines are equipped with the finest and fastest protection, carrier-pilot relays although high-speed distance relays[35] might alternatively be used. In either case the modified-impedance characteristic[21] would probably be used if the lines were long or heavily loaded or both. There is some trend toward use of this characteristic generally. Balanced-line protection[35] may also be used if the lines are paired, although high-speed distance or carrier relays are required to secure fast operation with one line out of service.

The 33-kv circuits (or higher voltages), often looped or interconnected, carry bulk power out through the territory served by the particular utility, to substations in the various towns, communities, and large industries. A looped 33-kv circuit may use directional-over-current relays with instantaneous trip attachments, both phase and ground, with selectively higher time settings each way around the loop, shown at the left in Figure 12. Impedance relays are considerably more likely to be used for the phase relays, as shown at the lower right. These would preferably be the high-speed impedance type, or alternatively the normal-speed impedance relay. Directional-over-current-inverse-time, or product-type relays would probably be used for ground protection. Loops or tie circuits involving short lines of 33 or 13.8 kv lend themselves well to pilot-wire protection[29] as in the center right of Figure 12.

Induction-type overcurrent relays, usually with instantaneous-trip attachments, for operation at the higher currents, will be found on a majority of the radial feeders, and the 4- or 2.3-kv primaries. With dual 13.8-kv feeders to a substation, directional-overcurrent relays would be needed at the load end. Over-current relays with instantaneous-trip attachments are used also on higher voltage lines, the instantaneous element being set for slightly less than the maximum current for a fault at the next bus.

Network feeders would usually be relayed at the supply end by overcurrent relays as shown at the upper right of Figure 12 or by high-speed impedance relays. If the transformers are ungrounded, the ground relays can be sensitive and high speed, thus clearing the majority of faults very quickly. At the load ends, feeder faults would be cleared by the network relays and protectors. These relays are sensitive reverse-power relays. These several schemes of line relaying will be described later.

Over-Current

The basic schemes of co-ordination by time-over-current and time-distance are shown in Figures 13, 14, 15, and 16. The general plan of co-ordination with overcurrent relays on a radial system is shown in Figure 13. The time shown in each case is the fastest operating time for a fault at the location of the next device in sequence. At lighter generating capacity the fault currents are reduced and all operating times increased somewhat, but because of the inverse-time characteristics of the relay the margins between successive relays also increase.

Normal-Speed Impedance Relay

Figure 14 shows the co-ordination secured with elements of the type shown in

Figure 8(a). Differential protection of a 3-winding power transformer

(b) Typical large regulating transformer protection

Figure 2(*z*), on a number of line sections in series. This may equally well be a loop, the two ends shown being at the same supply point. The relay is set for a definite current pickup, much as an over current relay. When this current is exceeded, the tripping time of each relay increases in direct proportion to the distance from the relay to the fault, except that the minimum time is about 1/4-second for a fault at the relay. Each relay is adjusted to trip in approximately 3/4 second for a fault at the next bus, or 0.4* second longer than the next relay characteristic at the subsequent bus, whichever is greater. This system has been quite widely used on medium voltage lines. An advantage of the impedance system is that the characteristics do not change materially with changes of generating capacity or switching out lines.

High-Speed Impedance Relay

The high-speed impedance relay has the stepped time-distance characteristic shown in Figure 15. This can be obtained for example by separate directional, impedance, and timing elements with contacts connected as shown in Figure 17.

The impedance elements Z_1, Z_2, and Z_3 are set for successively greater distances. These elements may be pure impedance elements, Figure 2(*i*), or may have the modified characteristics, Figure 2(*k*), as will be explained later. The directional element must be high speed, such as Figure 2(*h*), and closes only for faults in the desired tripping direction from the relay. The third-zone impedance element is used to start the timer that closes first a second-zone timing contact, T_2, and later a third-zone timing contact, T_3. The timer is quick reset.

Thus for a fault in the first 90 per cent of the section, known as zone 1, the contacts D and Z_1, operate, giving instantaneous tripping, usually within one cycle, as indicated in the timing chart of Figure 15. While the other elements also operate, their action in zone 1 is purely back-up because the circuit breaker has already been tripped. Thus in zone 1 the tripping time is that of elements Z_1 and D.

For the second zone, which extends approximately to the middle of the next section (if so set), contacts D, Z_2, and T_2 in series do the tripping, provided the fault lasts for the time setting T_2. If the fault is in the next section, it will be cleared by the proper circuit breaker in advance of T_2 operation. However, back-up protection is provided by the second zone extending into the next section. This also provides operation for bus faults if they are not previously cleared by bus-protective relays.

The third zone, corresponding to tripping through the contacts D, Z_3, T_3 is set if possible to completely overlap the next section, providing complete back-up protection. It must, of course, be timed selectively with the T_3 timing of the next section.

The flexibility of this arrangement in molding its characteristic to various section lengths, circuit breaker and relay times is apparent. The highly successful operation of several thousand such relays in service indicates that for practical systems, which depart in many ways from the simple ideal case represented in Figure 15, the flexibility is sufficient to secure in general the operation outlined.

In some cases the time-proportional-to-distance characteristic lends itself better to co-ordination with other back-up protection, but the high-speed first zone element is desired. For this purpose, these two elements have been combined to make available the time-distance curve shown in Figure 16.

High-Speed Reactance Relay

A 3-zoned step characteristic similar to Figure 15, is also obtained using reactance high-speed elements, Figure 2(*x*). In this case the action is controlled by a directional-impedance starting unit, Figure 2(*v*), to avoid operation on low reactance (unity power factor) loads. Operation of the starting unit and reactance or ohm unit results in immediate tripping for first-zone faults. Second zone operation is secured by changing the ohm-unit setting at the appropriate time by means of an auxiliary relay operated by the timer. The starting unit and timer determine the third zone operating characteristic.

Ground-Relaying

The vast majority of ground relaying used in the United States is essentially overcurrent, with direction where needed. The more common elements follow:

1. Induction-overcurrent relay with instantaneous-trip attachment. The instantaneous trip is set below the maximum ground current in the line for a fault at the next bus. Nonsimultaneous closure of the circuit breaker poles during load switching may result in momentary ground current sufficient to operate the instantaneous ground relays, where the relays are set sensitively. This has been avoided by connecting a residual-voltage-relay contact in series with the trip circuit. The latter does not operate during load switching operations.

2. As in (1) but with induction-directional element, Figure 2(*e*) controlling the induction overcurrent element. The directional element may be polarized either by residual voltage or bank-neutral current if available.

3. Product-type relay, combining current and direction. (Figure 2(*l*)). Using residual current and residual voltage (or bank neutral current).

4. Instantaneous-overcurrent elements can be used if the line terminates at the far end in a transformer that will not pass residual current.

5. Less frequently high-speed-reactance-ground relaying, one relay per phase, and arranged in steps similar to phase relays in Figure 15.

While 70 or 80 per cent of the faults on lines are ground faults, except on lines with overhead ground wires, it will be noted that the relaying is predominantly of the over-current type. This is due to the greater difficulty of securing trustworthy distance operation with ground relays and the better operation of current relays in ground relaying. These relays can usually be set sensitively since the load currents if balanced do not flow through the ground relay. Also more advantageous use can be made of the inverse characteristic since ground current dimin-

* With 8-cycle circuit breakers, 0.4 second is considered adequate for circuit breaker time plus margin.

ishes more rapidly as the fault is moved from one relay location to the next.

The difficulty of impedance measurement lies in the variable fault resistance of 0 to 50 ohms or higher depending on the fault, ground wires, and tower footing resistance. Reactance relays minimize the effect of this resistance, but it is still appreciable. Mutual effects from parallel lines must also be compensated for. Thus, while reactance relays are available, their use to date has been limited.

In Canada, good success is reported with one impedance element per phase using residual current and line-to-neutral voltage. The lines are steel tower lines with ground wires.

Pilot Wire Protection

Thousands of installations of a-c pilot wire relays have been made in the last several years, a majority of which have the following characteristics in common. Some function of the line currents at the two ends of the line is compared over a single pair of pilot wires. This comparison is made at a sufficiently low energy level that leased telephone lines or private pilot wires may be used interchangeably. A network, such as Figure 2(*r*), or other means, is used to combine the line currents so as to obtain a single discriminating quantity, (E_{rp}), which can be compared over the pilot wires. The net result is a pilot-wire scheme that will clear faults within the section without any time delay and will not trip for faults beyond the current transformers at either end.

Such relays are relatively easy to apply as their settings are independent of relays on other lines. Their high-speed action simplifies the problem of setting other relays on adjacent lines.

It is necessary to have pilot wires which remain intact at times of faults on the lines protected. It is not permissible for protective gaps to break down, solidly grounding the pilot wires, to protect them from induced voltages, or station-ground potentials, caused by the flow of fault currents. If the pilot wires are subject to such voltages, these must be estimated and a proper co-ordination arranged. The voltages are kept below the breakdown of insulation or the flashover of any direct gaps to ground by one or more of the following measures.[30–33]

1. Suitable insulation of pilot wires and direct connected terminal equipment.
2. Insulating transformers.
3. Two-winding neutralizing transformers.
4. Three-winding neutralizing transformers.
5. Balance coils connecting both wires to ground or sheath through gaps, but maintaining the high impedance of the balance coils between wires.

Figure 9. False-differential current caused by the d-c saturation of current transformers during the condition of an asymmetrical short circuit

The d-c time constant for the case shown is 0.14 second. The incoming transformers are assumed not to saturate. Thus the error current of the outgoing transformer is the differential current through the relay

(b). Linear-coupler bus-protection scheme

Carrier-Pilot Relaying

About 1,000 terminals of carrier relaying are now in use in the United States, divided chiefly between the directional-comparison and the more recent phase-comparison systems. The differences are actually of minor consequence since either system serves to provide instantaneous tripping of both circuit breakers for a fault anywhere on the protected line section. Each system requires the four elements, relays, transmitter-receiver, coupling capacitor, and line trap, as shown in Figure 18. The differences lie in the relays.

Directional Comparison System

One form of the directional comparison system utilizes the stepped impedance elements as its basic actuating elements (see section on High-Speed Impedance Relay). Corresponding second and third zone ground-over-current elements, Figure 2(*b*) are provided. The carrier control has the net effect of eliminating all second-zone time delay for faults within the protected section. This is accomplished by closing of the contact *RR*, Figure 17, whenever a fault is present and carrier is stopped because the direction of flow is "inward" at each end of the line.

The mechanism is indicated generally in Figure 18. Occurrence of a fault anywhere within reach of the third zone relays, closes Z_3 starting carrier and setting up a circuit so that the receiver relay will close if carrier is removed by some other action. If the fault is internal, *D* and Z_3 close, stopping carrier transmission from either end of the line. The receiver relays, *RR*, immediately complete the trip circuit. If the contact circuit *RR* is opened manually the carrier can be cut out and a stepped-distance relay scheme remains. Thus the carrier is thought of as simply eliminating the time delay in the end zones, indicated by the shaded areas in Figure 15. The stepped-distance elements and an inverse-time ground current element provide the back-up protection in this system.

Phase Comparison System

The phase comparison system differs functionally in that the current directions or phases at the two ends of the line are compared rather than the power directions. Networks are used to derive a single-phase function of the line currents as in the pilot-wire relay. This function may be referred to simply as the "current" at each end of the line since it is a measure of the several phase currents.

If the currents at the two ends of the line are in phase and of fault magnitude, carrier is transmitted on alternate half cycles of current from either end of the line, resulting in substantially continuous carrier on the line from one end or the other. For an internal fault the current

Figure 11. Protection of a 6-circuit bus using two multirestraint relays per phase

Figure 12. Composite power system illustrating typical protective problems and their solution

at one end of the line reverses or remains below the fault detector setting so that carrier is sent only half of the time. The relay is arranged so that this produces tripping. In this system, the carrier portion is purely pilot protection. Back-up protection must be added as an entirely separate entity. Stepped-distance relays, or simply directional-overcurrent relays are used for back-up protection.

A few of the factors considered in determining whether to use one or the other of these systems are the following:

Favoring the Phase Comparison System

1. Can be added for high-speed protection with any existing relay scheme for back-up.

2. No potential transformers are required. Low-tension potentials are sometimes adequate for back-up relays.

3. Inherently trip proof on out-of-step conditions. (Out-of-step blocking relays are included in the other scheme if needed.)

4. Not subject to trip by induced ground current from a parallel line.

5. Back-up relays entirely separate. Can take either high-speed or back-up out of service without affecting the other.

Favoring the Directional-Comparison System Using Stepped-Distance Relays

1. Applicable to multiterminal lines.

2. Provides better discrimination between loads (tapped from lines) and faults. When transformers are tapped along the lines, it is not desired to trip the line for faults on the low-tension feeders.

3. Can trip with fault currents less than twice load currents.

4. More flexible for system changes.

However, on many lines either system is entirely applicable and might equally well be used.

Back-up Protection

As mentioned earlier, in the event of failure of the proper circuit breakers to clear a fault, it is desirable to have some form of back-up protection to remove the fault from the system in the next best way that can be arranged within economic limits. The measures employed in present-day practice vary all the way from complete duplication of relays, circuit breakers, and tripping sources at one extreme to no back-up at all at the other extreme. The measures used in each case are somewhat a matter of opportunism as to what can be done conveniently, but more a matter of judgment and evaluation of the following factors.

1. Technical means by which back-up could be provided.

2. Importance of the section being backed up. That is, consequence to the system of failure of the primary protection, if one or the other of the various back-up possibilities is in use.

3. Cost of providing back-up protection in various ways.

4. Probability of faults, of the failure of primary protection, or of equipment failures that would cause costly or time consuming repairs if the primary protection should fail.

5. Consequences to the industrial processes or other loads being served if service is lost, momentarily, or for a long time.

To make these considerations more concrete a few examples may be cited. If a line fault hangs on due to a circuit breaker failure and is not cleared, the first hazard is that the line may be burned down resulting in a time-consuming repair job. The second is that the continued fault may cause the whole system to pull out of step and result in a complete shut down of an entire city area or

large system. Provision of back-up may remove one or both of these possibilities depending on the circumstances.

In an indoor station the failure of some piece of equipment to function properly, thereby leaving a fault uncleared, may result in a fire or explosion with extensive damage, which might have been avoided or minimized had some secondary means of clearing been in use.

Needless to say these considerations extend far beyond protective relays, into maintenance, testing and safety practices, air versus oil switchgear, building construction, protection of lines against lightning and other hazards and quality of major equipment. All of these should eventually be weighed to obtain the most favorable over-all service for the time, effort and cost involved.

In a system of transmission lines protected by overcurrent or distance-measuring relays, the relays for each circuit breaker can frequently be set to provide primary protection for the immediate line section and back-up protection for the next line section, as indicated by the characteristics of Figures 13, 14, 15, and 16. Then in event of the failure of a circuit breaker to clear for any reason, all other lines feeding that bus are cleared at their remote ends, with some time delay. This is the most common form of back-up protection.

Overcurrent relays are frequently used for back-up protection on lines equipped with high-speed distance, or pilot-wire or carrier relays. These also provide protection for the immediate line while the primary protection is taken out of service for the testing.

In many cases relays at one station, A, Figure 19, cannot reach through the bus of the next station, B, to a fault at the ends of the lines beyond. This is especially true if there is generation on the bus at station B, or if the lines beyond are very long, or both. Consideration is then given to some form of protection that will clear all other circuit breakers on bus B, if one fails to open for a fault. One scheme n use is to have the relays of each circuit breaker on bus B not only trip their circuit breaker, but also energize a time-delay relay. This relay will trip all circuit breakers on the bus, through the bus-auxiliary lock-out relay, if the protective relay does not open its contacts within a reasonable time, indicating that the fault has been cleared. This takes care of circuit breaker or trip-coil failure. Relay failure is backed up assuming that there is more than one relay element that should trip. However, it does not guard against battery failure or instrument-transformer or lead failures. Sometimes the back-up relays can be connected to different transformers than the primary protection but the only precaution normally taken with respect to the battery is good supervision.

Experience indicates that it is better economy to apply back-up relays to protect against other equipment failures than merely to back-up another relay, while using all the same accessories.

On some generator busses a partial-differential back-up is used to trip the complete bus section for feeder faults not cleared by the proper circuit breaker. The main sources, such as generators, transformers, and bus ties are totalized to operate these back-up relays. The relays are usually overcurrent and are given enough time to select with the main feeder protection.

In some very important stations complete duplicate sets of relays are used, operated from separate transformers to provide the back-up function. Also in certain large generating stations, with double circuit breakers separating major bus sections with power concentrations of the order of 200,000-kw load, the back-up partial-differential circuit not only uses separate current transformers but trips the other circuit breaker of the double-breaker combination. The partial-differential protection can often be arranged so that it backs up generator, reactor, and bus protection as well as feeder protection.

Since carrier, pilot-wire or distance protection is sometimes required to obtain 100 per cent selective primary protection, it is not always possible to obtain selective action of the back-up relays. There is some trend in the case of pilot-wire protection of short-line sections to cut the back-up relays in automatically when the supervision relays indicate that the pilot wires are inoperative. Some use is being made of carrier in a somewhat similar philosophy, to block certain back-up elements when carrier is being received.

Modified-Impedance Relays, Mho Relays

Increased use is being made of the mho and modified-impedance characteristics shown in Figure 2(u) and (k) for the protection of long heavily-loaded lines. It is desirable that the relays permit the maximum expected steady or swing loads without tripping. On long or heavily-loaded lines, and especially if high-speed reclosing is used, it becomes more and more difficult for the relays to distinguish between heavy swing loads and fault conditions. The modified-impedance relays or mho relays provide the improved discrimination necessary in these cases.

Their operation can best be shown by plotting on a single diagram the impedances corresponding to three things.

1. Faults on the protected line.
2. Heavy load swing conditions.
3. The relay characteristics.

These are shown for a simple case in Figure 20. Considering the simplified case of a two-machine system with all impedances having the same R/X ratio, let the system impedance be laid out on a resistance-reactance chart as the line $OABO'$ representing the impedance from one machine to the other. The transmission line being studied is a tie-line constituting the section AB, shown heavy of this total impedance. If R and X axes are drawn through A, as shown, the impedance with respect to these co-ordinate axes are those seen by the relays at A. Thus, the locus of impedances seen by the relay at A for a solid fault on the protected line consists of the line A-B, having

Figure 13 (left). Co-ordination of overcurrent protection on a radial power system

Figure 14. Co-ordination of relays having an operating time directly proportional to the distance (impedance) from relay to fault

Minimum operating time about 1/4 second

Figure 15. Ideal step-impedance-time characteristic

Figure 16. Coordination using relays having instantaneous first-zone impedance and time-proportional - to-impedance element for end-zone and back-up functions

impedances from zero up to the full line impedance.

It can be shown that if the generator voltages at the two ends of the system are equal in magnitude and are at first in phase, then are moved out-of-phase, resulting in load transfer over the line A-B, the impedance locus viewed from A is along the line L-L'. That is, the impedance seen by a relay at A, for the load condition, is the impedance vector drawn from the origin, A, to a point on the line L-L'. This line bisects O-O' perpendicularly. The no-load points, corresponding to zero angle between machines are at infinity either way along L-L', whereas the 180 degree out-of-phase condition is at the intersection, C. All intermediate loads are somewhere along the line L-L', the point L corresponding to power flow A to B and point L' to power flow from B to A.

The large circle with center at the origin, A, represents a pure impedance characteristic, as in Figure 2(*i*). The smaller circle having the same "reach" beyond B is a modified impedance characteristic, Figure 2 (*k*) or (*u*). It can equally well trip for all faults on the protected line but is less likely to trip for very heavy loads or load swings. Successively heavier loads are represented by progressing through points L, D, and E along the load locus. The modified characteristic taken with directional element, trips for faults or loads in the cross-hatched area F, while the pure impedance element trips also in the areas G and G'. Thus the modified characteristic permits heavier loads without tripping.

When carrier relaying is used so that tripping requires closure of the relay at each end of the line, the small circle, for the relay at A can be advantageously shifted further to the right, so that the combined action of this relay and its mate at the other end of the line limits carrier tripping to the restricted zone between the two arcs at H and H'. The back-up protection must be given sufficient timing to ride through swings or eliminated entirely except for a high-set, long-time element.

The modified impedance element provides for independent adjustment of the radius of the circle and the location of the center as shown in Figure 2(*k*) and hence makes possible the superior discriminating characteristics needed for long or heavily-loaded lines as outlined before. The mho-element characteristic has similar flexibility, Figure 2(*u*), but can most simply be arranged to pass through the relay point A.

Motor Protection

For the larger motors which are equipped with protective relays, the protection supplied varies with the importance of the service and whether automatic or not and whether attended or non-attended.

Many motors 500 horsepower and larger, and some smaller ones are protected by long-time (geared, 40-second) induction-type overcurrent relays set in the neighborhood of 150 per cent of maximum-load current, but with timing to permit the starting inrush of several-hundred-per cent current for several seconds. A typical case might be 600 per cent for ten seconds for an across-the-line-started induction motor, although these figures vary widely, depending on the application, and must be determined in each individual case. These relays will operate for a stalled motor for internal motor faults or for a heavy overload.

The overcurrent relays are usually provided with instantaneous-trip attachments set above the motor-starting current to trip quickly for severe faults in starter, leads, or motor.

Figure 17. Contact circuit for producing the stepped time-distance characteristic shown in Figure 15

Z_1 = first-zone impedance-element contact
Z_2 = Second-zone impedance-element contact
Z_3 = Third-zone impedance-element contact
T_2, T_3 = Timer contacts having separately adjustable time settings for second and third zones
D = Directional-element contact

Thermal relays are frequently provided in addition to the overcurrent relays, to provide more sensitive overload protection. Having a time constant of several minutes as contrasted with seconds for the overcurrent relay, they follow the motor temperature more closely. They will not protect the motor under stalled conditions, however, where the motor ventilation is missing, the overcurrent relay provides this function.

In automatic applications, and where starting in reverse would be serious, a phase rotation relay is used which closes contacts to permit a starting only if the phase sequence is correct and voltage is present on all three phases. This does not guard against phase unbalances which might occur during operation, however. For this purpose, a phase-balance current relay, Figure 2(*p*), is provided in many automatic schemes to trip if the 3-phase currents become excessively unbalanced. Time-delay under-voltage protection is frequently applied to guard against overcurrent or process damage, resulting from sustained operation at low voltage. However, where continuous operation is more important than motor protection this feature is eliminated or used for alarm only.

Thermal-alarm devices applied directly on the motors are becoming increasingly popular in attended stations where the operator can determine from the ammeters or other indications, the source of trouble.

Power House Auxiliaries

The power house is the heart of any electric system and its functioning rests on the motors which drive its fans, pumps, gates, and other auxiliaries. Hence reliability is paramount and in addition to provision of a most suitable power supply and spare units for certain auxiliaries, much attention has been given to the relay protection. A recent survey of United States practice[42] resulted in the following recommendations, attendance being assumed.

The 2,300-volt motors should use long-time-delay phase-overcurrent relays for overload and internal motor faults, set at approximately 150 per cent of rated current.

Figure 18 (left). Directional-comparison carrier-relay system including relays, carrier transmitter-receivers, coupling capacitors, and line traps

Dotted lines indicate symbolically the carrier controls

Figure 20. Modified-impedance characteristics provides improved selectivity between heavy-load swings and line faults

They also should be equipped with instantaneous overcurrent relays for short-circuit protection set above maximum-inrush current. If the auxiliaries are transferred the instantaneous relay must be set above a higher inrush current.

On essential motors* the time-delay overload relays may be used for alarm purposes only, and the instantaneous relays used to trip. In this case the time-delay relays can be set more sensitively than 150 per cent of rated current.

Low voltage motors (208, 440, 550 volts) should use a thermal device for overload protection, and an instantaneous-trip device for short-circuit protection.

In addition, the report notes the desirability of eliminating undervoltage protection except for alarm purposes, so that the loss of auxiliaries due to system disturbances will be minimized.

General Subjects

Brief mention will now be made of certain subjects and special relay problems in order to partly fill some large gaps still remaining in this picture of protective relaying in the United States.

Industrial Interconnections

When a line is tapped to an industrial plant having generation, it is common practice to segregate essential loads for operation from the plant generator and dump others in event of a line outage. If the same line is tapped for other plants, the problem arises of separating the plant under consideration from the line under conditions hazardous to its operation. One scheme in successful use on many industrial interconnections consists of separation based on any of three indications provided power flow has reversed and is toward the power company. The three indications are: under frequency, under-voltage, or generator overload. Any of these occurrences, provided power flow is away from the plant, is taken as sufficient cause for separating and at the same time dumping nonessential loads so that the remaining plant load may be brought within the capacity of the plant generation.

The relays normally employed are:

Induction-type overcurrent for generator overload.

Induction-type under-frequency relay.

Induction-type undervoltage relay.

High-speed-type 3-phase directional relay.

The generator overload relay is directional controlled so that it will not start timing unless direction in the interconnection has reversed.

Directional relays are also used, without the voltage, frequency or current fault detectors, for this purpose.

Three Terminal Lines

Lines having three or more terminals[26] are generally more difficult to protect than 2-terminal lines. Alternating current pilot wire protection is applicable in many cases although the limiting values of pilot-wire capacitance and resistance are less per terminal than for 2-terminal lines. Carrier schemes, particularly of the blocking type are applicable to multi-terminal lines. However, sequential operation of circuit breakers occurs if fault current of appreciable magnitude flows out at one terminal for an internal fault near another terminal. The first-zone impedance element nearest the fault, acting independent of carrier, opens the first circuit breaker, after which carrier is stopped by the directional elements permitting clearing of the other circuit breakers.

Figure 19. Problem of back-up protection

Out-of-Step Protection

Practically all utilities,[26] except those consisting of steam stations connected rigidly together electrically, have experienced system instability. Most utilities have experienced some undesired operation of fault-protective relays as a result of system instability. Quite a number of utilities attempt either to block line relays from tripping because of out-of-step conditions, or to set the relays so that tripping will occur at a preselected point. Out-of-step blocking on conjunction with carrier relaying is the method most commonly employed.

Synchronous frequency changers interconnecting two systems may suffer mechanical damage to shafts and couplings if permitted to operate with the systems out-of-step. The resulting power pulsations may be close to the natural frequency of the two-mass system composed of the two rotors with connecting shaft. Out-of-step relays are available which detect a slip cycle by the power reversal at high current and can be set to trip after two or three slip cycles, or before serious torque oscillations build up.

Quick clearing of faults by modern 8-, 5-, and 3-cycle circuit breakers and high-speed relays is well accepted as a measure of prime importance in improving system stability and reducing damage and permanent outages. Case after case could be cited where these improvements have been realized as circuit breakers and relays have been modernized up to present-day standards. High speed reclosing

* Essential motors are in this case defined as those motors whose failure results in the shut-down of generating capacity.

has been made possible by simultaneous operation of circuit breakers at the two ends of a transmission line by carrier-current or pilot-wire relaying. This measure is generally accepted as economically of greatest benefit in improving stability and service reliability. Three-pole[41] reclosing has been most widely used. However, there are a number of applications of single pole reclosing[42] which further enhance the stability by leaving the sound phases in service while the faulted ones are opened and reclosed.

Testing and Maintenance

Routine tests are made by many companies at quite frequent intervals such as one to three months, depending on the importance of the service. However, the major calibration tests are generally scheduled for periods more of the order of six months to two years. One year is a quite common period. There is a decided feeling that too frequent testing may cause more harm from mistakes and inadvertent damage than the good that is accomplished. The tests vary from the over-all or primary test in which current is passed through the primary of the current transformer, and the circuit breaker tripped by the resulting relay action, to much less complete checks. A quite usual procedure would be to remove the relays from service and test and calibrate on a load box, and to check the instrument transformers for continuity and grounds. The instrument transformer-relay circuit is grounded at only one point[44] so that the intentional ground can be lifted for this test. If feasible the circuit breaker may be tripped by closing the relay contact.

Conclusion

An attempt has been made to present a good many of the highlights of protective relaying as it is now practiced in the United States. Space has prevented even mentioning a great many schemes in successful use. It has been necessary to restrict the discussion to a few which the authors believe to be the more common. Quite copious references have been given to enable the reader to pursue further the subjects of particular interest. The three bibliography sections of the AIEE relay committee[1–3] are highly recommended as a guide to other relaying subjects of interest which are not touched on in this paper.

Discussion

C. E. Asbury (Commonwealth and Southern Corporation, Jackson, Mich.): This is a most excellent paper covering the principles and practices of the more commonly used relaying schemes in the United States. The concise descriptive material in the body of the paper, as well as the list of references and supplementary diagrams at the end of the paper, giving graphical representations of relay characteristics and fundamental elements of design, should prove to be a very useful reference.

As pointed out by the authors in their conclusion, no doubt due to space requirements, it has been necessary for them to limit mentioning a great many schemes which are in successful use. I wish to emphasize one type of bus protection to which the authors make a reference on page 8 of their paper. This scheme, referred to further in Steeb's paper which is listed as reference number 17, consists of instantaneous ground relays on each oil circuit breaker off the bus to provide an over-all bus ground protective scheme. Our general plan is to use instantaneous initiating ground relays on each circuit breaker having a source of ground current, and connect all of their contacts in parallel. The combination of these initiating relay contacts in parallel is connected in series with the back contacts of an instantaneous relay on each of the circuits connected to the bus. These back contacts provide blocking of the bus protection scheme for external faults. Directional blocking relays are required on feeders having ground sources. A time-delay relay is used to co-ordinate the initiating relays with the blocking relays to make certain that the blocking relays have time to open the circuit before the initiating relays close. Since this arrangement operates on the basis of individual instantaneous ground relays on each circuit breaker and does not have the current circuits interconnected, the bus protective scheme is independent of current transformer characteristics, which is very desirable. We have a number of these bus protective schemes in service at the present time and are well pleased with their performance.

A vast majority of protective relays in use in the United States are overcurrent, or directional overcurrent relays. In the major transmission systems, these overcurrent relays are being replaced rapidly by various forms of distance relays having greater load and swing ability. However, for economic reasons, there still remain a number of lower voltage systems where overcurrent and directional overcurrent relays are applied. During the past four or five years, most systems have been operated heavily loaded, and it has been necessary to increase settings on these overcurrent and directional overcurrent relays.

In many applications the limiting condition is load ability. That is, an upper limit is reached above which the relay cannot be set, and still provide proper system protection for minimum fault conditions. This setting may not be high enough for emergency loading conditions. A new relay has recently been developed to alleviate this situation. A modified impedance element is used for the directional element, and an overcurrent element is used to provide inverse time overcurrent characteristics to give selective tripping. The directional element determines the load ability of the relay and has essentially the same directional characteristics as those shown in Figure 2*M* of the paper. We are at present installing a number of these voltage restrained directional overcurrent relays for increased load ability and we believe they will find a wide application. Where overcurrent relays require greater load ability, instantaneous overcurrent and instantaneous undervoltage fault detectors are used. Contacts of these two fault detectors are connected in parallel and the combination in series with the overcurrent relay contacts.

As pointed out by the authors, many applications of instantaneous phase and ground relays have been made to supplement inverse time overcurrent phase and ground protection to provide high-speed protection for a portion of the line section. The instantaneous element is normally set below the maximum fault current at the next bus, and where these are not directional, it is necessary that they be set high enough not to operate for faults on the bus or lines behind the breaker. This latter condition often requires such a high setting on the instantaneous attachment, that little line protection is obtained. In some cases this inflow of fault current may be of such a magnitude as to prevent the application of instantaneous attachments.

Directional controlled instantaneous relays have recently been made available. These relays are available for both phase and ground protection, and extend greatly the application of instantaneous overcurrent protection. These directional controlled, instantaneous relays may be applied to lines where the infeed of short circuit current (the nontripping direction) is many times greater than the fault current on the line section (current in the tripping direction). We are using a number of these directional controlled, instantaneous relays for ground protection, and it appears that they will find wide application.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): The authors have done an excellent job in summarizing present-day relaying practices in this country. Their paper is a valuable addition to the literature. It will be helpful to both the practicing engineer and the student for whom relaying is a new subject.

In order to make the chapter dealing with generator protection more complete, I would like to suggest that a few words be added about the various methods of de-energizing the field of generators on operation of any of the protective relays, since such equipment is often considered a component of the relay scheme. It may also be mentioned that solid neutral grounding of generators is not considered good practice at the present time.

As for transformer protection, it seems to me that the recent report of the relay committee (reference 15 of the paper) indicated difficulties with differential protection due to magnetizing inrush currents, which do not seem to have been eliminated completely by the methods and special relays mentioned in this paper.

In future installations, consideration should be given to a combination of pressure-and-gas-actuated relays, since such relays are much more sensitive[1] than any kind of differential protection, free from the influence of inrush currents, and because they present an economical solution for smaller transformers. It is doubtful whether regulating transformers require two gas-actuated relays, since the development of gas in the separate tap-changing compartment is as natural, and without harm to proper designs, as the development of gas in an oil circuit breaker. Though protection is required for the transformer as such, it is hardly necessary for the rugged tap-changing mechanism, if the tap changer is placed in a separate compartment.

The difficulty of securing trustworthy distance protection on ground faults is open to question, since good results with relay schemes, originated by Dubuse and Douce, have been obtained in this country and abroad, in which line currents, residual current and line-to-ground voltages are fed to the impedance relays.[2,3] Schemes which apply selector relays[4] in addition seem to have distinct advantages over a combination of distance relays (for line-to-line faults) and inverse time relays (for ground faults), and would deserve wider application than they had in the past.

4. Control of Distance Relay Potential Connections, A. R. van C. Warrington. Electrical Engineering (AIEE Transactions), volume 53, 1934, pages 206–13.

E. L. Harder and W. E. Marter: The discussors have added useful information and comments to the paper which is necessarily brief on many subjects. Gross mentions that solid grounding of generators is not considered good practice at the present time.

The paper makes no recommendation in this regard. The recent report on present day grounding practices[1] mentions that 25.7 per cent of generating capacity is solidly grounded. It is the protection of these machines which is being discussed under that heading.

In general we concur with Gross' comments about pressure and gas actuated relays although we caution against misinterpretation of the statement that pressure and gas actuated relays are more sensitive.

It is the gas actuated relays used for alarm devices and not for tripping which are more sensitive. The pressure devices used for tripping have not been definitely proved more sensitive. In general,

alarm devices of various types have not been included within the scope of the protective relaying paper.

We concur that progress is being made in distance ground relaying.

Asbury has mentioned some recent relaying applications not mentioned in the paper which are of considerable importance. The paper covered only the more widely used schemes of protection.

A Method of Selecting Inherent Overheat Protectors Based Upon Motor Design Information

V. G. VAUGHAN
ASSOCIATE AIEE

WHEN the first motors were designed, it was entirely by cut and try methods. There was little or no knowledge about current carrying capacity of wires, rates of heat loss, magnetic characteristics of iron, and so forth. Today with the detailed information now available, it is possible to calculate for a desired performance with a reasonable degree of assurance that the expected performance will be attained.

Much of this information was obtained by building motors and running many tests. The knowledge gained by study of the data from these tests has produced the necessary detailed information for the modern methods used in designing and forecasting the motor performance.

Inherent overheat protectors are a relatively new product. They are just emerging from the trial and error stage. When one has the protectors there is still the design problem of applying the protector to the motor to produce the best engineered combination. As the protectors are emerging from the trial and error stage it seems desirable to start thinking about ways and means of reducing the problems of application of the protector to the motor to some sort of a scientific standard.

The object of this paper is to stimulate thinking in this direction and to describe a method developed for the selection of protectors by using motor design information for single phase fractional horsepower motors.

As in all preliminary investigations the results were obtained by testing motors, protectors, and the combination. Then by working backwards, empirical curves have been established for arriving at the proper protector to select for use in other motors of the same design as those used to produce the curves.

History of Inherent Overheat Protection

Inherent overheat protection can be divided into two basic types.

1. Where the thermal element is responsive to temperature only. This type of device has been used for years in large electric machines in the form of thermocouples and resistance coils.

2. Where the thermal element is responsive to both the flow of motor current through the protector and the ambient temperature surrounding the protector.

The writer's knowledge of such a device began with experimental work in 1924. At that time motor engineers were reluctant to consider making any provisions in the motor for mounting the protectors. Up to that time fractional horsepower motors depended on fuses, thermal cutouts or relays mounted remotely from the motor for thermal protection.

The first commercial application was made about 1929 to one of the early hermetic refrigerator machines. It is interesting to note that this original design and method of application is still in use by this manufacturer and his motor life in the field has been one of the best.

WHAT THE PROTECTOR SHOULD DO

From its name it is obvious that it should protect. If it is to be of benefit to the motor user, it must protect without limiting the motor's ability to do the maximum amount of work safely. This indicates that if we are to protect motors, we must know something about those features of a motor that will result in excessive temperatures.

Motor Temperatures

It is needless to go into the history of motor ratings based on temperature rise. It was introduced in the days when motor production was small and this method of rating was necessary to create a standard for the industry. It has been in use so long that it has become a tradition.

In order to keep this paper as simple as possible, let us confine our discussion to class "*A*" insulated motors. The AIEE standards say that class "*A*" insulation may be continuously used at temperatures up to 105 degrees centigrade. We know that the life of insulation is a function of its continuous operating temperature; the higher the continuous temperature, the shorter the life. This is illustrated by curves in Figures 1 and 2.

Figure 1 shows an average life of 2,000 days at 105 degrees centigrade, whereas Figure 2 shows a minimum life expectancy of 2,000 days at 105 degrees centigrade. The two authorities show the same basic time-temperature characteristic and only vary as to degree.

From Figure 1 we note a 2,000 day average life expectancy at 105 degrees centigrade and yet at 200 degrees centigrade, we see a minimum life expectancy of five days.

Due to the wide difference in values at the extremities of the curves in Figures 1 and 2, there is some feeling that a composite curve should be developed. The author suggests that this could well be an activity of the AIEE committee on insulation. Figure 3 is an attempt to further illustrate the fact that short periods at

Paper 48-187, recommended by the AIEE domestic and commercial applications and rotating machinery committees and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948. Manuscript submitted February 9, 1948; made available for printing April 7, 1948.

V. G. VAUGHAN is vice-president, Spencer Thermostat Company, Attleboro, Mass.

Figure 1. Effect of temperature on life of insulation (Scott and Thompson)

Figure 2. Effect of temperature on life of insulation (Miner)

higher than normal temperatures are no more destructive than longer periods at lower temperatures. The white area indicates the author's conception of how insulation life is reduced with higher temperatures.

In Figure 3 we have a line for 40 degrees centigrade ambient, the base line for rating motors. Then, above this is the 80 degrees centigrade line for full-load rating of open-type motors based on 40 degrees centigrade rise in 40 degrees centigrade ambient. When the motor is operating at temperatures of 80 degrees centigrade or lower, it is assumed that the motor is operating at full load or less than rated full load.

Above the 80 degrees centigrade we have an area with vertical lines that denotes a range of temperatures where it is assumed that the motor is operating with some degree of overload.

The vertical lines stop at 105 degrees centigrade which is the AIEE maximum allowable safe continuous operating temperature. It is recognized generally that the class "*A*" insulated motor can safely operate continuously at any temperature below 105 degrees centigrade.

Above the 105 degrees centigrade we have heavily shaded areas that taper with ascending temperatures. These shaded areas indicate that as class "*A*" insulation is subjected to temperatures in excess of 105 degrees centigrade, the operating time cannot be continuous and must be reduced, if we are to maintain a life equivalent to continuous operation at 105 degrees centigrade. This is accomplished by intermittent operation of the protector.

Temperature Limitations of Protected Motors with Class *A* Insulation

The preceding facts are the basis for the Underwriters' Laboratories adopting for inherent protected class "*A*" insulated motors 125 degrees centigrade as the maximum tripping temperature on running loads and 150 degrees centigrade as the peak temperature on stalled motor.

Motor Hot Spot Temperatures

Our temperature discussion up to this point has been general. It is well known that when a current flows in the motor winding, the temperature is not uniform.

Figure 3. Effective winding temperatures of protected motors

There is one spot that will be hotter than the rest of the motor and it is recognized generally that it is this hot-spot temperature that must be considered as the limiting temperature.

Temperature Measurement Methods

The traditional method of measuring motor temperatures has been the mercury thermometer. This method is neither sufficiently sensitive nor accurate for obtaining hot-spot temperature information for use in inherent overheat protector application work.

Temperature Rise

It has been traditional to assume that a given load current will produce a uniform temperature rise in the motor regardless of the ambient in which the motor is located. This assumption is not sufficiently accurate for inherent overheat protector application work as is seen in curves and table in Figure 5. The details of Figure 5 will be discussed later in the paper.

Temperature Information

It has been customary for motor engineers to make temperature tests at full load and at 125 per cent of full load.

For protector application work it is desirable to know more about the temperatures produced by load currents all the way up to the current to raise the winding to 125 degrees centigrade.

All of the necessary temperature information can be obtained from a curve

Figure 4. Heat run curve, 1/6 horsepower 4-pole split phase open motor

(Figure 4) plotted from data obtained by running the motor until stable temperatures are reached; first at full load current, second at a value "A" of overload current and third at a higher value "B" of overload current as shown on the curve.

In order to obtain a good degree of accuracy these tests should be run in a room where the ambient is maintained at a constant value. The necessity for this is illustrated by curves in Figure 5. These curves are plotted from results obtained by first running at various values of load in 26 degrees centigrade ambient and then in 40 degrees centigrade ambient.

These curves clearly indicate the degree of error in assuming that a given value of current will produce the same temperature rise in a motor regardless of room temperature. The higher the motor temperature, the greater this error. This suggests that some day a new method of rating motors must be devised. In addition to running temperatures, information must be available on locked rotor temperatures. Under locked conditions it is well known that the motor will overheat in a short time so the necessary locked rotor information is one of time versus temperature. This is illustrated in Figure 6.

As the time required to heat the winding is very short, a standard test method has been adopted in order to get uniform results. Temperatures are measured by thermocouple, locked current is produced by a constant voltage source, and the tests are made in a constant temperature room. The recording of data is not started until the windings stabilize at test room temperature. After recording initial temperatures, the potentiometer is set ahead for a 40 degrees centigrade reading. When the potentiometer indicates that the winding has reached 40 degrees centigrade, the time and current data are recorded and the potentiometer is set ahead for a 60 degrees centigrade reading, and so forth.

Table I. Locked Rotor Test on 1/6 Horsepower Split Phase Motor Run in Constant Ambient 26 Degrees Centigrade With Constant 115-Volt Supply

Open Motor			Enclosed Motor

Mechanical Factors Affecting Motor Temperature

Motors are built with many mechanical variations such as open or enclosed, with or without fan, castiron or aluminum end shields, and various methods of mounting. Few, if any, of these variations have any effect on the initial locked rotor heating characteristics, as shown in Table I.

The tests that produced these data were run as described in the preceding paragraph. The locked rotor curve for the open motor test is plotted in Figure 6. The test on the enclosed motor was made after the openings had been securely taped closed so as to prevent any ventilation. It is to be noted that the time-temperature data for both the open and closed rotor tests (Table 5) are practically the same.

Nearly all mechanical variations do affect the running temperatures as illustrated by heat run curves in Figures 7, 8, and 9.

Motor Line

In fractional horsepower motors it is common practice for each manufacturer to have a standard external diameter punching for a group of motors; as in this example from 1/20-horsepower, 8-pole motor up to and including 1/3-horsepower, 2-pole motor. The internal diameter of stator punching and rotor diameter for 8-, 6- and 4-pole motors are the same. The 2-pole motor usually has a smaller rotor and a smaller internal diameter in the stator punching.

For the smallest rated motor of a given speed, the wire is of relatively small diameter and the shortest stacking of laminations is used. As the horsepower for this speed is increased the wire size is increased and a greater amount of iron is required. An example of this is shown in Table II.

Any of these motors can be produced with any of the possible mechanical variations. Obviously, as mechanical variations are introduced which will affect motor temperature, it may be necessary to change the size of wire used in the winding.

Correspondingly, if the mechanical arrangement of all of these motors is kept the same, we could expect that the winding temperature would be related to wire size. In order to investigate this a series of heat-run curves similar to Figure 4 were run on such a line of motors. Table III shows the wire sizes of these motors.

The amperes which raise the winding temperature to 115 degrees centigrade in a room ambient of 26 degrees centigrade is recorded in Table IV.

If the circular mills are plotted against amperes required to reach 115 degrees centigrade, the curves in Figure 10 will be the result showing the expected relationship between wire size and running temperature.

In other words, if we had to design a new motor in this line with special characteristics, and if we knew the wire size, we could forecast the current which would heat the winding to 115 degrees centigrade in a 26 degrees centigrade room.

Protector Information

When inherent overheat protection was first introduced, it was common practice to develop a particular protector for a particular motor application.

As the art developed the next step was to produce a line of protectors embodying all possible combinations of available parts. The first method was so restrictive that it made application prohibitive in cost.

The second method was satisfactory as long as the number of combinations was not too great. Figure 17 shows the various physical sizes of disk-type protectors available.

At the present time inherent overheat protection has outgrown both of these methods and now standard lines are being developed in which the ultimate trip characteristics are similar and ratings are spaced as nearly as possible by uniform percentage steps illustrated by curves at the left side of Figure 11. The short time characteristics give satisfactory locked rotor protection to the majority of existing commercial motors. This is illustrated by the series of curves at the right side of Figure 11.

There will always be some motors in which the short time characteristics of the standard line of protectors will be either too long or too short. For these motors it will be necessary to use a special protector. Figure 14 illustrates how today, with practically the same ultimate trip characteristics, the short time can be controlled over a rather wide range. The solid line curves in the center represent the standard line protector. The broken line curves at the top represent the maximum short time possible with a special protector for the illustrated ultimate trip, and the broken line curves at the bottom represent the minimum short time possible to obtain with a special protector of approximately the same ultimate trip rating.

Ultimate Trip

Analysis of the ultimate trip curves (left-hand side of Figure 11) shows that for the proper selection of a protector we need to know both the current that

will heat the winding to the selected limiting temperature and protector ambient. From the curves developed in Figure 10, we can read the ultimate trip current for 115 degrees centigrade for a given wire size. We must now develop a means of determining the protector ambient temperature.

Protector Ambient Temperature

This temperature is very difficult to measure directly as part of the protector is in contact with the motor frame which is at one temperature and another part of the protector extends out into the air within the motor frame where it is subjected to both the air temperature and radiation from the winding.

By standardizing protector test methods it has been possible to simulate average conditions and get reproducible protector ultimate trip curves.

To correlate the protector data with motor test data, the previously mentioned line of motors was run with protectors and by working backwards as in Figure 13, the effective protector ambient is obtained. Curve A–C is a heat run curve on a motor. Protector number *10* produced an ultimate trip temperature of 115 degrees centigrade at 4.15 amperes. The ultimate trip curve of protector number *10* crosses the ordinate for 4.15 amperes at 94 degrees centigrade, which we can assume is the effective protector ambient temperature for 115 degrees centigrade winding temperature and 4.15 amperes. When developing this information it will not be easy to get protectors which will give exactly 115 degrees centigrade ultimate trip temperatures. In these cases it is possible with a little experience to interpolate with a sufficient degree of accuracy.

The values of effective protector ambients listed in Table V were taken from the ultimate trip curves of the protectors used to get an ultimate trip of 115 degrees centigrade for each of the motors in the line. These values were plotted along with horsepower and inches of iron to produce the series of parallel curves in Figure 14. The curves are plotted for a uniform spacing even though the actual test results here did not produce as smooth a set of curves as the winding temperature data. It is assumed that these variations are due to inability to get a higher degree of testing accuracy.

Selecting a Protector for Ultimate Trip

We now have sufficient information to select a protector to give us an ultimate trip of 115 degrees centigrade for a motor of similar mechanical design to the line we have tested. To illustrate, we will assume that we have from our motor design information a 1/6 horsepower, 1,750 rpm motor with a main winding of 2,025 circular mils and 2 inches of iron.

From the 4-pole curve in Figure 10 we find that 5.1 amperes will produce a 115 degrees centigrade winding temperature, and in Figure 14 we find that a 1/6 horsepower motor with 2 inches of iron will give an effective protector ambient temperature of 88 degrees centigrade.

The nearest ultimate trip curve (number *9*) in Figure 11 to the intersection of the 5.1 amperes ordinate and the 88 degrees centigrade abscissa will be the protector that will produce approximately 115 degrees centigrade winding temperature at ultimate trip in this 4-pole motor with 2,025 circular mils in the main winding and 2 inches stacking of iron.

While we have previously touched on the question of locked rotor temperatures, we have made the protector selection based on running performance. Obviously this has been done because a motor is built to run and, therefore, running conditions should be the most exacting requirements for the protector. On the other hand locked rotor produces the most

Figure 10. Line of split phase long-hour open motors, 60-cycle

Wire size (circular mils) versus amperes to heat main winding to 115 degrees centigrade in 26 degrees centigrade room

Figure 12. Range of short time trips or approximate ultimate trip conditions

Figure 15. Empirical curve for line of split phase fractional horsepower motors

destructive temperatures so that a satisfactory protector must protect the winding in case the motor becomes stalled.

Locked Rotor

The most difficult period for protecting a stalled motor is when the motor is cold for then the protector must function entirely from the heat produced by passage of the stalled current through the protector. During this very short period the mass of the motor and its radiating area has little or no effect on rate of heating. This leaves us with the heating rate as a function of the current density.

We must, therefore, investigate the highest current density winding of the motor which in most single-phase motors is the phase or start winding.

In Figure 6 we have the time-temperature curve for a winding operating at 33,500 amperes per square inch. If the current density had been greater or less than existed in the test that produced this curve, then the time to reach 125 degrees centigrade would have been less than or more than the 17 seconds shown in Figure 6. Stalled rotor tests similar to that plotted in Figure 6 were run on many motors, not only the line mentioned previously in this paper but other motors with very high and very low current densities. By taking the time required to reach 125 degrees centigrade from each of these curves and plotting them against their respective current densities, we get the curve in Figure 15. From our motor design information we know the current density (amperes per square inch) of the windings for the motor under consideration. From curve Figure 15 we find that the 33,500 amperes per square inch require 17.4 seconds to heat the winding to 125 degrees centigrade.

We have selected previously protector number 9 for running protection of this motor. From our design information we have a locked rotor current of 17.2 amperes. Applying this locked rotor current of 17.2 amperes to the short time curve of protector number 9, right side of Figure 11, we find that the tripping time of this protector in a 25 degrees centigrade room is ten seconds. This time is less than the time required for this same value of locked rotor current to heat the winding to 125 degrees centigrade and, therefore, we can expect the first tripping of the protector to prevent the winding temperature from reaching 125 degrees centigrade.

If the selected protector would have allowed overheating of the winding, then a lower standard rating could be used resulting in lower ultimate trip temperatures or a special protector as illustrated in Figure 12 could be used.

In some few cases the selected standard protector might not allow a particular motor, when starting, to stay on the line sufficiently long to come up to speed. In this case a higher rating standard protector could be used with a correspondingly higher ultimate trip temperature during running or a special protector which had a longer short time characteristic as illustrated in Figure 12.

The type of protector used in this work and shown by the standard line curves, Figure 11, will in most cases give a temperature cycling curve shown by curve in Figure 16. It is noted that the winding temperature at first cutoff is 121 degrees centigrade. The winding temperature after a few cycles reaches 139 degrees centigrade and after reaching stable cycling temperatures the winding temperatures repeatedly attain 128 degrees centi-

grade cutoff temperatures. This is acceptable as it is less than the Underwriters' allowable temperature of 150 degrees centigrade peak temperature.

Discussion

All data and curves used in this paper are based on actual test data and design information. Tables VI and VII were prepared in order to show the type of test.

No doubt there are other methods of approach to this problem of selecting the proper protector for a motor during its design. It is hoped that this paper will stimulate thinking along this line and result in simpler and better ways of accomplishing the desired results.

This work has indicated that more accurate temperature testing is required than has been common practice. In the higher temperatures where the heat curve flattens out Figure 4, it is necessary to get very accurate current readings. It is desirable to make these tests in constant temperature rooms and with accurate controls of voltage and load currents.

The least consistent test results obtained in this study are the protector ambient temperatures from which curves in Figure 14 were plotted. Fortunately, at the point where the ultimate trip curves are used the errors encountered have a minimum effect on the motor winding temperature. No doubt continued work in this field will refine this information or will bring forth a new and better method of arriving at the proper effective protector ambient information.

Conclusions

Where sufficient ground work has been done it is possible to preselect protectors from physical design characteristics of motors with a reasonable degree of accuracy. Expanded use of protected motors will result (in time) in a new method of rating motors.

The author recommends that:

1. Motor engineers attempt to develop simpler methods of protector selection.

2. The AIEE committee on electrical insulation develop curves to replace those shown in Figures 1 and 2.

3. The AIEE adopt standard locations and methods of applying thermocouples to motors.

Discussion

L. C. Schaefer and C. G. Veinott (Westinghouse Electric Corporation, Lima, Ohio): The author is to be commended for his studies made in an attempt to cut the time required for the selection and application of inherent overheating protectors to motors. Anyone who has faced the problem of making such applications to literally hundreds of different motor designs appreciates the need for short cuts.

We were a little surprised that Vaughan included in his definition of inherent-overheat protector a device responsive only to temperature. In our practice, we have considered that inherent-overheating protection was provided only by a device responsive both to motor temperature and to the current traversing the motor, as described in Gano's fundamental patent (United States Patent Number 1,693,379). In practice, the disk-type thermostat requires an auxiliary heater traversed by current in order to obtain locked-rotor and running protection. Temperature-sensitive thermostats are used on integral horsepower motors, but these afford only running protection; locked-rotor protection is obtained by the use of an external current-operated device.

Vaughan mentions as the first commercial application of a disk-type thermostat its use on a hermetic refrigerator. This application pioneered in two important respects.

1. The thermal protective device gave true inherent overheating protection because the device was responsive to both temperature and current.
2. The device automatically reset itself.

At that time, the usual practice in domestic refrigerators was to use a manual-resetting current-operated device located inside the refrigerator. Now, the trend towards the use of dome-mounted automatic-reset protective devices is well established, a tribute to the sound engineering pioneered in 1929.

While discussing the history of built-in thermal protection, we should point out that it was used commercially in a limited number of electric drills in 1928. Built-in overload protection was introduced on fractional horsepower motors about 1931.

Vaughan's method undoubtedly gave satisfactory results for the line of motors tested. How practicable his approach would be for other lines of motors needs to be established. Fundamentally, the ideal application would be one in which the temperature of the bimetal disk followed closely the hot-spot temperature of the winding under all conditions of load, ambient, and so forth. With this kind of an application the disk would be set to operate at the desired hot-spot temperature of the winding with full assurance that complete protection would be afforded against all conditions of load, ambient temperature, line voltage and ventilation. We believe an ideal selection method should take into account directly the opening temperature of the disk, whereas Vaughan used it only indirectly. Moreover, it appears to us to be a rather artificial approach to determine the protector ambient temperature by use of curves; why not measure it directly and eliminate any errors due to errors in the ultimate tripping curves of the thermostats? Our experience with this type of approach has given inconsistent results. The author confesses the same difficulty when he reports that the curves in Figure 15 "are plotted for uniform spacing even though the actual test results here did not produce as smooth a set of curves as the winding temperature data." These kinds of tests are difficult to take with consistent results and the author is to be commended for his honesty.

V. G. Vaughan: I offer the following as a rebuttal of the discussion offered by Schaefer and Veinott.

The major part of this discussion seems to be a question of effective ambient temperature of the protector.

The selection and application of inherent protectors would be very simple if there was any temperature that could be measured that would give this effective protector ambient correctly. In our work we have found that even in the same line of motors changing from one type of material in the end bell to another, or a different speed or changing the ventilation, changes the protector ambient temperature so much that there are no consistent values that can be obtained by measurement or calculation, and that is the reason we have resorted to the empirical method of running tests and arriving at the values to be used as a result of numerous tests on a given line.

I do not want to imply that the method used here is the only good one. As a matter of fact as indicated in the paper it is my hope that this paper will stimulate other people to make investigations which will result in their adopting a standard method of selecting protectors with less work than is now required by this cut and try method.

Mercury-Arc Power Converters in North America

AN AIEE COMMITTEE REPORT

Part I. Introduction

THIS is a report on the present status of the design and application of mercury-arc power converters on the North American continent. It was prepared because there was a need of a comprehensive review of this subject, for the benefit of those who have not kept up with the voluminous literature. A selected bibliography is given at the end of the paper, and numerical references are made to it in the text.

The operation of a mercury-arc power converter is based on the valve action of a mercury arc in vacuum, which permits currents to flow in one direction only—from the anode to the mercury-pool cathode.

The mercury-arc rectifier was developed in the United States by Cooper-Hewitt, following his introduction of the mercury-arc lamps in 1901. The first commercial application was made in 1904 to convert alternating current to direct current for battery charging. The rectifier was of the glass-bulb type.

The development of metal-tank rectifiers was started in the United States and in Europe several years later. The first commercial installation was made in Europe in 1911, and several installations were made in the United States between 1913 and 1915. This development was then suspended in the United States. It was resumed about ten years later, following the introduction of metal-tank rectifiers of European make in 1924. The application of glass-bulb rectifiers was continued during the intervening period.

The use of metal-tank rectifiers in the United States and Canada, for converting alternating-current to direct-current, has increased rapidly since 1925. Their aggregate capacity is now about 5,500,000 kilowatts. Most of the earlier applications were for electric railway service. During the last ten years the electrochemical applications have become the largest. Rectifiers aided in the large-scale expansion of aluminum and magnesium production during the war. Other important applications are for industrial service and mining.

Mercury-arc rectifiers have practically superseded rotating-type a-c to d-c converters for d-c voltages over 200 volts and ratings over 150 kw, except for rolling mill drives and other applications requiring a wide range of voltage adjustment. The following characteristics of mercury-arc converters are responsible for their ascendency over rotating machines:

1. They are static equipment, are quiet in operation, require no special foundation, and can be installed in locations unsuitable for rotating machines.

2. They can be switched on and off like a transformer, require no synchronizing and no polarity checks, and are adaptable for automatic or remote control. They can operate on any commercial power system frequency and are relatively unaffected by a-c system disturbances. Faults can be cleared quickly without damage and with only a short service interruption.

3. They have a relatively high efficiency over the greater part of the load range, and their idling losses are low.

4. The operating and maintenance costs are generally lower than for rotating machines.

While the chief application of mercury-arc converters has been for converting a-c power to direct current, they can be used also for converting d-c power to alternating current, or as frequency changers. Two noteworthy frequency-changer installations were made about five years ago in steel mills, to provide a flexible nonsynchronous tie between the 60-cycle and 25-cycle power systems for the transfer of power between them.

Until about ten years ago all mercury-arc rectifiers were of the multianode type, with 6, 12 and 18 anodes per tank. The trend had been to increase the number of anodes per tank to obtain a higher current rating per rectifier. This trend was reversed by the introduction of the single-anode type ignitron, followed several years later by the excitron. Single-anode tanks or tubes, each containing one main anode and a cathode, are assembled in groups of six and twelve to make up a unit.

The single-anode type rectifier has largely superseded the multianode type in the United States, for the following reasons:

1. Lower arc drop and consequently higher efficiency.

Figure 1. Elementary single-anode, pool-cathode mercury-arc rectifier tube

Paper 48-188, recommended by the AIEE electronics and electronic power converter committees and approved by the AIEE technical program committee for presentation at the AIEE summer general meeting, Mexico, D. F., Mexico, June 21-25, 1948. Manuscript submitted March 10, 1948; made available for printing April 5, 1948.

This report was prepared by a working group of the AIEE electronic power converter committee which included H. Winograd (chairman), Allis-Chalmers Manufacturing Company, Milwaukee, Wis.; C. R. Marcum, Westinghouse Electric Corporation, East Pittsburgh, Pa.; L. W. Morton and H. C. Steiner, both with the General Electric Company, Schenectady, N. Y.

2. Simpler maintenance, because individual tanks or tubes can be removed and replaced without affecting the others of the group.

3. More adaptable for quantity manufacture, because a larger number of smaller duplicate parts are involved.

4. Fewer sizes are needed, because higher ratings can be obtained by increasing the number of tubes per group.

Single-anode mercury-arc rectifiers are made in the pumped-tube and sealed-tube construction, and several types are described in Part II of this paper. Sealed tubes are generally applied for rectifier units of lower rating, while pumped rectifiers are usually applied for units of higher rating and for heavy-duty service. While there is no rigid dividing line, most of the existing sealed tube installations have unit ratings of 1,000 kw or less. However, there is an increasing trend towards the application of sealed-tube rectifiers for higher ratings.

Part II. Construction of Rectifiers

Basic Tube

The basic elements of a single-anode rectifier tube are shown in Figure 1. The main anode, the mercury-pool cathode, and the auxiliary electrodes are enclosed in a vacuum envelope. The electrical connections to the main anode and the

auxiliary electrodes are made through vacuum-tight insulating bushings in the envelope. The cathode connection is usually made on the envelope. The flow of current consists of a stream of electrons from the cathode to the anode. By convention, the direction of current flow is opposite to the direction of electron flow. Electrons are emitted at cathode spots on the mercury surface, which can be initiated by the arc-starting (ignition) electrode.

The flow of current can start only when there is a cathode spot on the mercury, when the anode is positive with respect to the cathode, and when the potential of the control grid (if present) is such that the electrons are permitted to reach the anode. The flow of electrons ionizes the mercury vapor in the arc path, and positive ions of mercury neutralize the negative space charge of the electrons. Large currents can flow with a relatively low voltage drop in the arc, of the order of 15 to 25 volts at rated current, depending on the rectifier design. The magnitude of the current is determined by the circuits to which the rectifier is connected. The control grid has no influence after the flow of current has started and can regain control only after the current flow has stopped.

Baffles are placed in the arc path to shield the anode from the mercury vapor and droplets evolved at the cathode or to provide deionizing surfaces. Rectifier tubes are cooled by water circulated through a water jacket over the vacuum envelope or through a cooling coil, to remove the arc losses and control the mercury vapor pressure. Air-cooled rectifiers have also been used. The mercury vapor condenses on the cooled surfaces and returns to the cathode. The main anode, grid, and baffles are usually made of graphite. The vacuum envelope is made of steel.

Rectifiers are subjected to a degassing process, as part of the manufacturing procedure, to remove occluded gases from the internal parts. These parts are heated to or above their operating temperature, by passing current through the rectifier or by other means, and the liberated gases are removed by vacuum pumps. The vacuum envelopes of sealed tubes are also heated to degas their inside walls.

Types of Tubes

There are two general types of single-anode mercury-arc rectifiers: the ignitron and the excitron, which differ in the method of cathode excitation. In the ignitron the cathode spot is initiated during each cycle of the a-c voltage by means of an ignitor of refractory material immersed in the mercury. The start of the conducting period in the cycle is controlled by timing of the ignition, and there is no arc at the cathode during the non-conducting period of the cycle. In an excitron a cathode spot is maintained continuously, while in operation, by means of a pilot arc from an excitation anode. The start of the conducting period of the main anode is controlled by a control grid.

Pool-cathode tubes are made in two types of construction, the pumped tube and the sealed tube. Pumped rectifiers are provided with vacuum pumps, and the tubes are connected continually to

the evacuating system. The anode plate or cover of a pumped tube is demountable and is sealed to the vacuum tank by a gasketed joint. The tube can be opened on site for reconditioning, when necessary. In sealed tubes the metal-to-metal joints are welded, and the joints of insulating bushings are made by fusing the insulator to metal. The evacuating connection is sealed after the degassing process. The parts of the tube which are in contact with the cooling water, including the water jacket, are made of stainless steel, in order to minimize corrosion and the seepage of hydrogen ions into the tube.

Tube Ratings

The current and voltage ratings of a mercury-arc pool-cathode tube are determined largely by thermal limits and arc-back frequency. An arc-back is the failure of the rectifying action, due to the formation of a cathode spot on the anode when it is negative with respect to the cathode, which results in a flow of current in the reverse direction, from cathode to anode. For low d-c operating voltages, of about 300 volts or less, arc-backs are rare, and the current rating is established generally by the safe operating temperature of some of the internal parts and the

Figure 9. Output characteristics and current wave shape for ignitor excitation circuit of Figure 8

anode bushing. For higher d-c voltages, the current rating of a tube is reduced as the operating voltage is increased, in order to reduce the probability of arc-back. The average arc-back frequency on rectifier units is usually less than one per anode per year. With proper protection, arc-backs cause no damage, and the equipment is returned to service immediately.

Single-anode pumped tubes are made in a number of sizes, for d-c ratings up to 1,000 amperes per tube, at a d-c output voltage of 250 volts. Sealed tubes are made in several ratings up to 400 amperes direct-current per tube, at 250 volts. Generally, the same tube can be used for a range of d-c voltages up to about 900 volts, the current rating being reduced as the voltage is increased. However, the kilowatt rating per tube is increased as the voltage is increased.

Pumped and sealed mercury-pool tubes are made also for higher d-c operating voltages and are described in the following.

Ignitrons

The operation of an ignitron is based on the ability to initiate a cathode spot on a mercury pool, at a precise and controllable instant during each cycle, by passing a pulse of current through an ignitor partly immersed in the mercury. This development was announced by Slepian and Ludwig in 1933.[3] The ignitor, shown in Figure 7, is a pencil-like rod made of a refractory material such as boron carbide. Several types of pumped and sealed ignitrons are described herein.

Pumped Ignitrons

In Figure 2 is shown a cross section of a typical pumped ignitron tube for operation in the range of 250 to 900 volts direct-current. The vacuum tank is cooled by water circulated through a water jacket. The anode is made of graphite and is surrounded by a graphite grid. The ignitor is mounted at the end of a long rod which is connected to an inlet in the side of the tank. The immersion of the ignitor in the mercury pool can be adjusted externally by means of adjusting screws. An auxiliary anode is used for maintaining cathode-spot excitation over the normal conducting period of the main anode.

The insulating seals for the connections to the main anode, grid, ignitor, and auxiliary anode are constructed of "Mycalex," a fused mixture of glass and mica bonded to special steels. A heater is provided around the anode and grid seals to prevent condensation of mercury on the anode assembly. A baffle is mounted over the exhaust opening in the tank to keep the mercury condensed in the exhaust pipe from striking the anode when returning to the tank. The anode plate is sealed to the vacuum tank by aluminum gaskets tightly clamped between flanges.

Figure 3 shows the construction of a pumped ignitron for operation at 3,000 volts direct-current.[10] The general construction of this ignitron is similar to that of the lower-voltage types except that two grids are used. The vacuum-tight anode seal is made of an alloy steel "Kovar" fused to its matching glass. The seal is enclosed by a porcelain bushing which serves as a support for the anode assembly. The vacuum tank is cooled by water circulated through copper cooling coils soldered to its surface. A steel cooling coil is provided inside the tank, with its terminals brought through welded joints in the tank. The internal and external coils are connected in series. A graphite baffle, mounted on insulating supports, is placed above the mercury-pool cathode.

Sealed Ignitrons

Figure 4 shows the general construction of the 100-ampere and 200-ampere sealed ignitron tubes.[11] The vacuum envelope and water jacket are made of stainless steel. The glass-to-metal seals[5] of the insulating bushings are made with "Kovar" or "Fernico," an iron-nickel-cobalt alloy, fused to a matching borosilicate glass. The expansion characteristics of the glass and metal match over the temperature range to which the seal is subjected during manufacture, so that little stress remains in the completed seal and nearly the full strength of the glass is realized.

Figure 11. Excitation circuit for a 6-tube pumped excitron rectifier

Figure 12. Cross section of 200-ampere sealed excitron

Grids are not required in these sizes of sealed ignitrons. Two ignitors are usually installed, but only one is used; the second is a spare in case of accidental damage to the first. The auxiliary anode provides cathode excitation over the normal conducting period of the main anode, which permits the main-anode current to approach zero without arc instability.

Figure 5 shows the construction of a 400-ampere sealed ignitron.[40] The general construction and the materials used are the same as for the smaller tubes, shown in Figure 4. With the increased physical dimensions, however, a grid is required to control the effects of residual ionization following the conducting period and to attain the desired tube rating.

In Figure 6 is shown the construction of a pentode high-voltage ignitron.[23] The name "pentode" is derived from the fact that the tube has five principal electrodes: an anode, three grids, and a cathode. The outermost grid serves primarily as a shield, to isolate the anode structure from ionization in the main body of the tube. The next grid is used for control purposes. The innermost grid divides the potential between the main anode and the cathode, by an external potentiometer connection. Six of these tubes, in a 6-phase double-way circuit (see Figure 37), have a capacity of 7,500 kw at a d-c operating voltage of 17.6 kv, as a power rectifier or a power inverter.

Ignitron Excitation

Figure 7 shows an ignitor complete with its supporting band for use in pumped or sealed ignitrons. The ignitor point is immersed in mercury to approximately half the length of its tapered section. Mercury does not wet the ignitor material, and a negative meniscus is formed in the mercury at its junction with the ignitor. Cathode spots are formed at this junction when a pulse of current, of the order of 10 to 20 amperes, is passed from the ignitor into the mercury. Ignition of the cathode spots is caused by the thermal and potential gradients produced by the current. When the tube starts conducting and the cathode current increases, the initial cathode spots divide and form new spots. The number of spots depends on the current, each spot providing emission for approximately 15 to 20 amperes of cathode current. The active cathode area on the mercury surface assumes a circular form, with the ignitor at the center, and with a diameter proportional to the current. There is insufficient time for the cathode spots to reach the tube wall during the normal conducting period, and it is unnecessary to insulate the mercury pool from the wall.

The firing characteristics of an ignitor[45,46] are influenced by a number of factors such as immersion depth, ignitor temperature, rate of rise of the ignitor current, as well as by the ignitor design. The effective ignitor resistance decreases with deeper immersion or increased temperature. Variation of immersion depth is due to wave motion on the mercury surface. For a lower resistance, a lower voltage and a higher current are required for ignition. Firing time depends on the rate of current rise. While these factors are complex, from the practical standpoint it is only necessary to define the highest required values of voltages, current, and time to insure satisfactory performance.

The most direct method of supplying the required ignition current is to divert part of the main-anode current through the ignitrons. This is the principal method used for ignitors employed for resistance-welding control; the ignitor is connected to the anode terminal through a thyratron tube. However, this method cannot be used where the load current drops below the value required for ignition, which is the case for most rectifier applications; a separate excitation system is then employed.

Nearly all separate excitation systems are of the energy-storage type.[16,17] Figure 8 shows a typical circuit for a pair of ignitrons, which are connected to phases 180 degrees apart. For a 6-phase rectifier consisting of six ignitron tubes, three such circuits are required. They are connected to a 3-phase a-c supply, derived from the same line as the main-anode voltages. In operation, the capacitor C_3 is charged by the a-c voltage, through the linear reactor. As the capacitor voltage increases, an increasing current flows through the nonlinear reactor. When the voltage across C_3 rises to a predetermined value, the core of the nonlinear reactor becomes saturated, so that its reactance drops to a very low value, and the energy stored in C_3 is discharged through the ignitor to start the cathode spot. This occurs alternately in the two ignitrons during successive half-cycles of the a-c voltage.

The autotransformer provides a return circuit for the capacitor current. The metallic rectifiers prevent the flow of reverse current through the ignitors, which could damage them. The phase or time position of the ignition pulse with respect to the main-anode voltage is obtained by varying the direct current in the control winding of the phase-shifting saturable reactor. The auxiliary anodes of the ignitrons are connected through resistors to an a-c voltage obtained from a transformer, as shown at the right of Figure 8.

Figure 9 shows the output volt-ampere characteristic of the ignitor-firing circuit in Figure 8, and the pulse-current wave shape. The point on the characteristic at which ignition occurs is determined by the ignitor resistance, as indicated by the resistance lines.

Excitrons

Pumped Excitron

A cross-section view of a pumped excitron tube is shown in Figure 10.[28] The main anode is supported by a steel stem, which is brought through a ceramic insulator on the anode plate with gasketed vacuum-tight seals covered by mercury. The anode is enclosed by a perforated control grid. The mercury pool of the cathode on the bottom of the vacuum tank is enclosed by a quartz ring.

The arc space of the tube is surrounded by a helical cooling coil made of steel tubing, which is insulated from the tank and is supported by insulating seals on the anode plate through which the coil terminals are brought out. The coil serves a dual purpose: it is used for cooling the rectifier and condensing mercury vapor; it also shields the tank to prevent

transfer of the cathode spot from the mercury to the tank wall. The turns of the coil are separated by narrow gaps, which permit passage of mercury vapor and gases but prevent arc-through. The gases are exhausted by the vacuum-pumping system to which the tank is connected through a bellows-type vacuum valve. The cooling water is circulated through the cathode water jacket and the cooling coil in series.

The excitation anode, used for starting and maintaining a cathode spot, is supported by the lower baffle and insulated from it. It is connected to an insulated lead-in on the anode plate by a wire passing through a ceramic tube. The excitation anode is connected to the cathode through an external circuit, which is provided with a source of direct current, as shown in Figure 11. The arc-starting device consists of a nozzle-shaped plunger in a well at the bottom of the tank below the mercury pool, and an ignition coil over the well. When the coil is energized, the plunger is pulled down against a spring and ejects a jet of mercury which short-circuits the excitation anode to the cathode and closes the excitation circuit. When the jet is broken an arc is started with a cathode spot on the mercury surface. The arc is maintained as long as the excitation circuit remains energized.

The main and excitation anodes, the grid, and baffles are made of graphite. The other internal parts, except the insulators, are made of steel. The tank supports serve as the external cathode connection. The anode connection is made at the top of the anode stem.

Excitation Circuit

The excitation and grid-control circuits of a 6-tube excitron rectifier are shown in Figure 11. The d-c excitation supply is obtained from a 3-phase a-c source through a transformer and a selenium rectifier. The excitation anode of each excitron is connected to the positive terminal of the d-c supply through a reactor, resistor, and a relay. When voltage is applied to the excitation transformer, the ignition coils are energized and start the excitation arcs. The excitation current operates the relays (*R1*, *R2*, and so forth) which open the circuits of the ignition coils. The d-c excitation supply is about 35 volts, and the excitation current per tube is about 8 amperes.

The control grids of the excitrons are connected to the 6-phase secondary of a small grid transformer through current limiting resistors. The neutral point of the grid transformer is connected to the cathode terminal, in series with d-c bias voltage. The point in the cycle at which the grid-to-cathode voltage becomes positive, to permit the main anode to fire, can be regulated by varying the bias voltage. The a-c voltages of the grids have a definite phase relation to the voltages of the main anodes. Instead of using a variable bias, the firing points of the main anodes in their voltage cycles can be controlled by shifting the phase position of the grid a-c voltages, by means of a phase shifter ahead of the grid transformer.

Sealed Excitron

A cross-section view of a sealed excitron tube is shown in Figure 12. The vacuum tank and its water jacket are made of stainless steel. The insulating anode bushing consists of a number of circular disks with interposing layers of vitreous enamel, which are fused together into a vacuum tight assembly. The vitreous enamel serves as the insulating medium. The vacuum envelope is shielded from the arc by means of a perforated shield.

The arc-starting device consists of a steel plunger with a cup-shaped cap. It floats in the mercury and makes contact with the excitation anode when there is no excitation current. The ignition coil is connected in series with the excitation circuit, as shown in Figure 13. When a d-c voltage is applied to the excitation circuit, current flows through the ignition coil and the excitation anode to the cathode. The plunger is pulled down by the ignition coil, breaking contact with the excitation anode to establish the excitation arc. As long as the excitation arc is maintained, the plunger is held down in the well, under the mercury pool, by the current in the ignition coil. If the excitation arc should go out, it will restart automatically as long as the excitation-supply voltage is applied to the circuit. The excitation current is about 7 amperes per tube.

Part III. Rectifier Units

Connection Diagram

A diagram of connections of the power circuits of a typical 6-phase rectifier unit is shown in Figure 14. It consists of a rectifier transformer, a rectifier, and switching equipment. The rectifier transformer is used for transforming the a-c line voltage to the voltage and number of phases required for obtaining the desired d-c voltage of suitable wave shape.[1,10] Most of the mercury-arc rectifier units have six or twelve phases. The transformer winding which is connected to the a-c line is called the a-c winding, and is connected usually in delta or wye. The winding connected to the rectifier is called the d-c winding. The d-c winding in Figure 14 has a 6-phase double-wye connection and consists of two Y-connected windings with their neutral points joined by an iron-core reactor called an interphase transformer (I T).[1] The two windings with their rectifying elements operate as two 3-phase rectifier groups in parallel, but produce a d-c voltage with a 6-phase wave shape. The midpoint of the interphase transformer constitutes one d-c terminal of the rectifier unit. This is the most generally used connection for mercury-arc rectifiers. Other rectifier transformer connections are given in references 1 and 37 of the bibliography.

Figure 13. Excitation circuit for sealed excitron tube

Figure 14. Typical power-circuit diagram of 6-phase rectifier unit

Arrows indicate current flow during an arc-back

The rectifying elements serve as unidirectional switches to connect the phases of the transformer d-c winding to the d-c circuit during a portion of their voltage cycles. In Figure 14, one-half of the total direct current flows through each 3-phase group, and is conducted in sequence through each of the three phases of a group during about one-third of a cycle. The position of the conducting period in the cycle of each phase voltage can be controlled by means of the control grids or by cathode ignition timing (for ignitrons). This control is used for regulating the d-c voltage and is called phase control.

Protection

The circuit breakers shown in Figure 14 are used for connecting the rectifier unit to the a-c and d-c circuits and for protection against overloads and arc-backs. An arc-back is the major fault in a power rectifier. It is a failure of the rectifying action which results in a flow of current in the reverse direction, from cathode to anode. An arc-back imposes a short-circuit on the rectifier transformer and on the d-c circuit, limited largely by the impedance of the transformer phase to which the faulted rectifying element is connected. Current flows to the faulted rectifying element from the other elements, as indicated by the solid arrows in Figure 14. If other sources of d-c power are connected to the d-c circuit, reverse current will flow into the faulted rectifying element from the d-c circuit, as indicated by the broken arrows in Figure 14.

An arc-back must be interrupted quickly to avoid possible damage to the equipment, because the arc-back current can reach values of the order of 50 to 100 times the rated current of the rectifying element and the transformer phase to which it is connected.[20,21] The fault current from the other phases can be interrupted by tripping the a-c circuit breaker. The fault current from the d-c circuit can be interrupted by tripping the d-c circuit breaker. If an anode circuit breaker is used, the fault currents from both sources can be interrupted by tripping the circuit breaker pole in the circuit of the faulted rectifying element, without opening the a-c and d-c circuits. Although anode circuit breakers were used as early as 1931, most rectifier installations prior to 1940 were protected by a-c and d-c circuit breakers. High-speed anode circuit breakers were introduced in 1940, for the protection of rectifiers in an aluminum reduction plant. They have been used for most of the rectifier installations in aluminum and magnesium reduction plants in the United States since then. They have been applied also for other rectifier installations, when better protection and greater operating flexibility is required. Better protection is provided by the anode circuit breakers because they are faster than a-c circuit breakers.[14,22] If an anode circuit breaker is used, the a-c circuit breaker can be eliminated, and protection against a possible fault in the rectifier transformer is provided either by fuses or by some other circuit breaker in the a-c supply circuit. In that case the transformer is connected to the a-c circuit by disconnect switches which are capable of interrupting the transformer exciting current.

When an anode circuit breaker is used, a d-c circuit breaker is usually provided also, for protection against excessive overloads. The anode and d-c circuit breakers in most installations are tripped by reverse current. Sometimes the d-c circuit breaker is provided with an overload trip also. When an anode circuit breaker is not used, the a-c circuit breaker is tripped by a time-delay overload relay for overload protection and by an instantaneous relay with a higher setting for arc-back protection. In installations where the reverse current from the d-c circuit can reach high magnitudes during an arc-back, high-speed anode circuit breakers (if used) or d-c circuit breakers are employed, with an interrupting speed of less than one cycle, to interrupt the circuit before the current attains a high value.

For d-c operating voltages of 750 volts or less, it is the present practice in the United States to use high-speed anode or d-c circuit breakers when the connected capacity on the d-c bus exceeds 2,500 to 3,000 kw. A semi-high-speed d-c circuit breaker is used when the anode circuit breaker is of the high-speed type. For higher d-c voltages, up to 3,000 volts, only high-speed d-c circuit breakers are employed.

The arc-back current to the faulted rectifying element from the other rectifying elements can be suppressed by applying a sustained negative voltage to the control grids (grid blocking) or by interrupting the cathode excitation. The rectifying elements which are not conducting at that time will be prevented from starting. The others will be prevented from restarting after their currents have dropped to zero. The backfeed current from the d-c circuit can be interrupted only by opening the circuit. Arc suppression by grid or excitation control cannot be relied on for full protection and must have back-up protection by circuit breakers, in case it does not suppress the fault current.

Auxiliaries

The tubes of a pumped rectifier unit are mounted on a base and are connected to the evacuating and cooling equipments. These auxiliaries and their connection with the rectifier are shown diagrammatically in Figure 15. Each rectifier tube is

Figure 15. Diagram of pumped rectifier unit with its evacuating and cooling auxiliaries

Figure 16. Typical over-all efficiency curves of mercury-arc rectifier units, as a function of the load, for several d-c operating voltages

connected to a vacuum header through an individual valve. The header is connected to two vacuum pumps in tandem, a mercury-vapor pump and an oil-sealed rotary pump. The mercury-vapor pump consists of a cylinder containing a pool of mercury, which is heated by an electric heater. The mercury vapor rises through a nozzle and is deflected downward towards the cooled walls of the cylinder, carrying along the gases which have diffused into the pump from the rectifier tubes. The mercury vapor condenses, while the gases are drawn into the rotary vacuum pump. The rotary pump consists of a cylinder with an eccentrically-mounted rotor and sliding vanes. The gases received from the mercury-vapor pump are compressed by the vanes and discharged to the atmosphere through a check valve and the oil. A vacuum valve between the two vacuum pumps closes automatically when the rotary pump stops, to keep the oil from backing up into the mercury-vapor pump. The mercury-vapor pump is cooled by water or air. The vacuum pipes are also cooled to prevent transfer of mercury between the rectifier tubes and the vacuum pumps.

Two types of vacuum gauges have been used for measuring the vacuum of mercury-arc rectifiers. In the McLeod vacuum gauge, a sample of the gas in a bulb is compressed into a measuring tube by raising the mercury in a well to a preset height in a tube alongside the measuring tube. The difference in the levels of the mercury in the two tubes is a measure of the gas pressure and can be read on a scale calibrated in microns. A micron is the pressure exerted by a column of mercury 0.001 millimeter high.

The operation of the hot-wire vacuum gauge is based on the fact that the thermal conductivity of a gas is a function of its pressure. A wire having a high temperature coefficient of resistivity is enclosed in a tube which is connected to the vacuum system. The wire is connected as part of a Wheatstone bridge and is supplied with a constant heating current. The lower the pressure of the gas the lower is its thermal conductivity, and the higher is the temperature and resistance of the wire. The resistance is therefore a measure of the gas pressure and is indicated by a vacuum meter calibrated in microns. Contacts on the vacuum meter, or a relay in parallel with it, can be used for controlling the vacuum pumps and for protecting the rectifier against operation with a poor vacuum. The normal operating pressure of a rectifier, as measured by the vacuum gauges, is usually below five microns.

Most of the heat generated in a rectifier by the arc-drop losses is carried off by the cooling system. In Figure 15 the cooling water is circulated between the rectifier tubes and a heat exchanger by a motor-driven water pump. A water expansion tank is connected to the recirculating system, to permit expansion of the water when it is hot and to provide a water head on the system for preventing entrance of air. In the heat exchanger, the circulated water is cooled by raw water from a supply, which is discharged to a drain after passing through the tubes of the heat exchanger. The temperature of the recirculated water is regulated by a thermostatically-controlled valve, which controls the flow of raw water. The temperature of the recirculated water is maintained usually at some value between 45 and 55 C. Sometimes heaters are installed in the rectifier cooling circuit to keep the temperature from dropping too low during periods of light load.

A corrosion inhibitor, such as sodium chromate, is usually added to the rectifier cooling system. If the cooling circuit should be exposed to freezing temperatures, an antifreeze solution is added. In installations where a reliable supply of raw water is not available, or the cost of water is too high, a water-to-air heat exchanger can be used. The rectifier water is circulated through a radiator which is cooled by a fan or blower. In many rectifier installations the cooling equipment is insulated from ground and kept at the same potential as the rectifier. The connection to the raw water supply is then made through an insulating pipe, such as a rubber hose, as shown in Figure 15. If the cooling equipment is grounded, insulating water connections are used between this equipment and the rectifier.[8,44]

Sealed-tube rectifiers, of course, do not have any evacuating system. The tubes usually are mounted in a metal-enclosed cubicle of a unit-type substation. Many sealed-tube rectifiers, particularly for lower capacities, are cooled by tap water and may not require any water pumps. For underground mine service, portable substations are generally used, and the equipment is mounted on low-headroom mine cars. The tubes are cooled by a circulating water cooling system with a water-to-air heat exchanger.

Part IV. Rectifier Characteristics

The important quantitative characteristics of mercury-arc rectifier units are

Figure 17. Over-all efficiency of mercury-arc rectifier units at rated load, in function of the d-c operating voltage

Figure 18. Typical voltage-regulation curves of rectifier units

I—For 6-phase double-wye transformer connection

II—For 6-phase star transformer connection

efficiency, voltage regulation, and power factor. These characteristics are discussed in the following, and typical values are shown by curves. The use of phase control is also considered.

Efficiency

The over-all efficiency of a rectifier unit is the ratio of the power output to the total power input, or the ratio of the power output to the power output plus the losses. The efficiency is determined usually by calculation from the measured segregated losses in the component parts of the unit. The losses of a typical unit consist of the core and load losses of the rectifier transformer, the arc-drop losses in the rectifier tubes, and the power required for tube excitation and the auxiliaries.[27]

The rectifier transformer loss is usually in the range of 1.5 to 2.5 per cent of the kilowatt output, depending on the kilovolt-ampere size and the voltage. The arc drop in the rectifier tubes ranges from 15 to 25 volts, depending on the size and type. The arc drop of a tube changes little with the load current, and the same tube can be used for a wide range of d-c operating voltages. The per cent loss in the rectifier therefore decreases as the d-c voltage is increased.

The excitation losses are of the order of 200 to 300 watts per tube. The auxiliary losses include the power required for such items as the water pump, vacuum pumps, and vacuum gauge, and usually constitute a fraction of one per cent of the rectifier output. Sealed-tube rectifiers have no evacuating equipment, and may not require a water pump when cooled by tap water. When water heaters or anode heaters are used, they generally operate only intermittently, and their losses are not considered in the efficiency calculation.

Typical over-all efficiency curves of rectifier units for d-c operating voltages of 250, 600, and 3,000 volts are shown in Figure 16. The curves are fairly flat over the greater part of the load range. The efficiency at rated load, as a function of the d-c operating voltage, is shown in Figure 17.

Voltage Regulation

Voltage regulation is the change in output voltage between rated load and no-load (or light load), expressed as a percentage of the rated voltage.[27] The d-c output voltage of a power rectifier decreases as the load current is increased. The drop in voltage is due to the reactance of the rectifier transformer and the a-c supply circuit, the resistance losses in the rectifier transformer, and the increase in arc drop with current.

The voltage drop due to reactance is the major component of the regulation. It is caused by reduction of the terminal voltages of the transformer d-c winding during the commutation periods between phases (see Appendix). The reactance drop depends on the type of transformer connection used and is directly proportional to the load current.[1]. The voltage drop due to the transformer resistance is also directly proportional to the current. The increase in arc-drop with current is only a few volts between light load and rated load and is usually proportional to the current. The regulation curve of a rectifier nuit is therefore a straight line.

Typical regulation curves of rectifier units, for two types of rectifier transformer connections, are shown in Figure 18. Curve *I* applies to a 6-phase double-Y connection (see Figure 14), which has been the circuit most generally used for mercury-arc rectifiers. The voltage rises about 15 per cent between light load (0.5 to 1.0 per cent load) and no load, because there is insufficient current for excitation of the interphase transformer. This voltage rise can be suppressed by connecting a ballast resistance when the load current drops to zero. For most applications this is not required. Curve *II* shows the regulation for a 6-phase star connection. Although this connection is used rarely, the curve is given to illustrate the effect of the rectifier circuit on the regulation.

Power Factor

The power factor of a rectifier unit is the ratio of the volt-amperes to watts at the a-c line terminals of the rectifier transformer. The power factor is less than unity for two reasons.

1. The a-c line current is nonsinusoidal and contains harmonic components which do not contribute to the power input but increase the rms value of the current.
2. The fundamental component of the line current is displaced in the lagging direction from the line-to-neutral voltage, because of the transformer and line reactances.[27]

As the number of rectifier phases is increased, the harmonic components of the current decrease and the power factor increases, approaching the power factor of the fundamental component. Typical power factor curves of 6-phase and 12-phase rectifier units are shown in Figure 19.

Voltage Control

It is often desired to control the ouput voltage of a rectifier for various reasons, such as to maintain a constant voltage on the d-c bus or a constant output current, for starting a motor at reduced voltage, or for controlling the motor speed. The output voltage can be changed by means of taps on the rectifier transformer. However, this method is not practical for continuous control of the voltage, unless load tap-changing equipment is employed.

For most rectifier applications, phase control is used for controlling the output voltage. The voltage is reduced below its normal value by retarding the firing points of the anodes in their voltage cycles by means of grid or ignition control (see Appendix). This method is illustrated by the inclined parallel lines in Figure 20, which are voltage-regulation lines for several values of the phase-control angle of retard. The angle can be changed continually and smoothly by means of a small rheostat or regulator. The horizontal line in Figure 20 illustrates constant-voltage control, for maintaining rated voltage from no load to full load. The difference between this line and the top regulation line represents the amount of phase control required; the angle of retard has to be varied between 0 and 20 degrees.

When phase control is used, the a-c line current is shifted in the lagging direction, which lowers the power factor by approximately the same ratio as the reduction of

Figure 19. Typical power-factor curves of rectifier units, without phase control

I—For 6-phase unit
II—For 12-phase unit

hot output voltage. This is shown by the power-factor curves in Figure 21. Curve *I* is for operation without phase control, curve *II* for 10 per cent reduction of voltage by phase control, and curve *III* applies to constant-voltage control as represented by the horizontal line in Figure 20.

Phase control also increases the duty on the rectifier tubes and the probability of arc-back. Only the amount of phase control actually needed should be used. When phase control is required, a range of about 15 per cent is usually provided in the control, but the full range is used infrequently.

Part V. Application of Rectifiers

General

Since their introduction in 1924, metal-tank mercury-arc rectifiers have become the accepted alternating- to direct-current power converters in North America, for most applications requiring d-c power of about 200 kw or more, at d-c operating voltages of about 250 volts and higher. The increase in the fields of application was a gradual process and was the result of improvements in the performance of rectifiers, development of new types, and pioneering by individuals and companies in new applications. This process is continuing.

The characteristics of rectifiers largely responsible for their preference over rotating-type converters were given in Part I. They are stationary and quiet, are simple to install and operate, have a high-efficiency and a low-maintenance cost. There are other specific advantages in the operation of rectifiers. There is no problem in parallel operation of rectifiers, because their polarities are fixed, reverse current cannot flow normally, and their voltages can be controlled easily and quickly. They are also adaptable for parallel operation with rotating machines. They can be returned to service quickly following an outage or power interruption, an important consideration in electrochemical plants and many industrial applications. They cannot feed into a fault on the a-c system and usually can ride through such faults without tripping. Being water cooled they can be installed in places where ventilation would be a problem.

Several problems were encountered in the application of rectifiers. In the earlier years they were cooled by raw water, which caused corrosion on the vacuum tank and water jacket. This was overcome by using a recirculating cooling system with a heat exchanger, which has become standard practice for pumped rectifiers. When rectifier installations were made on high-capacity a-c and d-c power systems, some failures occurred on rectifier transformers, due to high fault currents during arc-backs. This was solved by using high-speed circuit breakers and by improvements in transformer design. Such failures rarely occur now.

The harmonics in the d-c output voltage and the a-c line currents sometimes cause interference in telephone lines exposed to the a-c or d-c circuits. Interference from the d-c circuit, which has occurred only on railway systems, was eliminated by filtering the output voltage.[8] Telephone interference from the a-c systems supplying large rectifier installations in electrochemical plants was a serious problem. It was solved by multiplying the number of rectifier phases, for a group of units operating in parallel, by shifting the phase voltages of individual units.[12] There have been few cases of telephone interference from a-c systems supplying small rectifier installations. Such interference can be eliminated sometimes by changes in the power system or telephone circuits. Filters can be used to reduce the flow of harmonic currents into the system when other remedies are not possible.[8]

Electric railways were the first large users of d-c power to adopt rectifiers, because of their high all-day efficiency at the relatively low-load factor encountered in railway service. Quiet operation, ability to take high-load swings, and adaptability for automatic control were other considerations favoring rectifiers.

The application of rectifiers for electrochemical service came next, following the development of high-current multianode rectifiers rated at 5,000 amperes. The first installation was made in a Canadian zinc plant in 1929, with rectifiers of European manufacture. Applications for hydrogen and chlorine plants followed several years later. In 1938 the first large rectifier installations were made in aluminum reduction plants, in the United States and Canada. The production of aluminum was expanded greatly during the war, and this industry has become by far the largest user of mercury-arc rectifiers. Several large rectifier installations for production of magnesium also were made during the war. Rectifiers were adopted for electrochemical service because they are stationary equipment and have no commutator, are more stable than rotary converters under system disturbances and can be re-started quickly following a power outage, are simpler to operate, and their operating and maintenance costs are lower.

The extensive application of rectifiers for 250-volt constant-voltage industrial service, in steel mills and other industrial plants, followed the development of the single-anode type rectifiers with their improved efficiency at this voltage. The development of sealed-tube rectifiers extended the field of application to lower ratings, between 150 and 400 kw, where motor-generator sets were used formerly. Rectifiers are given preference in this service for the same reasons as for the other fields of application. They have a higher all-day efficiency than rotating machines. They can be placed in locations close to the load center and are simple to operate.

The increasing use of rectifiers in coal mines, for supplying d-c power at about 275 volts, is another consequence of the development of sealed tubes. Unit ratings of 200 to 600 kw are generally used, and many of the units are portable.

A start has been made in the use of mercury-arc rectifiers with a wide range of phase control for variable-speed motor drives. Another recent application is

Figure 20. Voltage-regulation curves of a rectifier unit, illustrating the operation of phase control for regulating the output voltage

their use for field excitation of large high-speed turbine generators, as a substitute for direct-connected d-c exciters. High-voltage mercury-arc rectifiers have been applied for supplying plate power to radio-frequency oscillators, when several hundred kilowatts or more are required. This field has been limited so far, and its future growth depends on the use of higher power radio stations and increased power for radio-frequency electronic heating in industry.

Another recent development is the application of mercury-arc rectifiers in electronic frequency changers. One type of frequency changer is used for interconnection of a-c power systems through a nonsynchronous tie. Another type converts low-frequency power to a higher frequency for induction heating and melting of metals.

The various applications of rectifiers discussed in the preceding paragraphs are covered more fully in the following sections. Service requirements and methods of operation are described, and some typical power-circuit diagrams and illustrations of installations are shown.

The power-circuit diagram and component equipment of a typical rectifier unit were described in Part III. The a-c circuit breaker and rectifier transformer may be placed indoors or outdoors. The rectifier with its auxiliaries, the d-c and anode circuit breakers, and the control equipment are indoors. The rectifier is insulated from ground, except when the positive d-c terminal is grounded. Sealed-tube units generally are built as indoor unit-type substations. The equipment is mounted and wired in metal-enclosed cubicles, which are lined up in sequence according to the power circuit. The rectifier transformer is between the a-c circuit breaker cubicle and the rectifier cubicle, which is followed by the d-c circuit breaker cubicle.

Table I is a summary of the estimated kilowatt capacity of rectifiers for various applications, installed or on order in the United States and Canada, up to January 1, 1948. Rectifiers that have been transferred from their original application to a new application are included under the new application.

In addition to the capacities in Table I, rectifiers with a total capacity of about 618,000 kw were manufactured in the United States for export to countries outside of North America. About two-thirds of that capacity was for production of aluminum, about one-fourth for transportation service, and the balance for other applications.

Railway Service

Voltages and Ratings

Rectifier unit sizes in the range of 500 to 3,000 kw are used for railway service; most of them, however, are 1,000 kw or higher. Three classes of d-c voltages are used for electric railways—600, 1,500, and 3,000 volts. By far the largest number of rectifier installations are for 600-volt service. This voltage is used for street railways, subways, suburban, and interurban lines. It is used also for some electrified sections of railroads. The higher voltages are used for suburban and interurban service and for main-line electrification.

There are three classes of ratings for conversion equipment used on railways.[27] All three have a rating of 150 per cent of rated current for two hours, following continuous operation at rated load. This overload rating is intended to take care of the morning and evening rush-hour periods on urban and suburban lines. The three classes of ratings differ in regard to their short-time overloads, following operation at rated load. These overloads are intended to take care of the load swings during starting and acceleration.

(A) Class I, for light-duty service, as on street railways, has a one-minute rating of 200 per cent of the continuous current rating.

(B) Class II, for medium-duty service, encountered on rapid-transit systems such as subways, has a one-minute rating of 300 per cent of rated current.

(C) Class III, for heavy-duty service, as for main-line railroad electrification, has a 5-minute rating of 300 per cent of rated current, to take care of the longer acceleration time required for heavier trains.

Substations[27]

On street railway systems the substations generally are distributed over the system, with one or two units per station. This is done to reduce the length and size of d-c feeders and to maintain a stable voltage on the trolley wire. On rapid-transit lines and railroads the substations usually are located along the line, at spacings depending on the voltage and load. The quiet operation of rectifiers and the nonrequirement of special ventilation have made it possible to place the substations in residential areas, or other locations, selected on the basis of economic and engineering considerations.

The rectifier substations usually are unattended and are controlled automatically or by supervisory control, with automatic reclosing in case of a trip-out due to a fault.[7] When full-automatic control is used, the rectifier units are started and stopped by a time switch or by load demand. Load-demand control is used in substations which have long idling periods. The rectifier is started when the d-c line voltage drops below a predetermined value for several minutes, indicating that a load is approaching; it is stopped when the load drops and remains low for 10 to 15 minutes. In substations having two or more units, additional units are started, in a predetermined sequence, when required by increased station load, and are shut down when the load drops off.

The a-c circuit breakers and rectifier transformers are placed outdoors when that is permissible. In densely populated areas all the equipment is usually placed indoors. When space is limited or ventilation is inadequate for self-cooled rectifier transformers, water-cooled transformers are used. On most railway systems the negative side of the d-c circuit is connected to the running rails and is therefore grounded. The positive ter-

Unit rated at 3,000 kw. Rectifier transformer is water cooled

minal of the rectifier is connected to the d-c bus through a single-pole d-c circuit breaker.

Most of the rectifiers in railway service were installed before the single-anode rectifiers were developed and are of the multianode type. Pumped single-anode rectifiers were used in practically all the installations made since 1940. Recently, several sealed-tube units rated at 1,000 kw were put in operation. In Figure 22 is shown a view of a rectifier installation in railway service.

New York Subway Rectifiers

The largest installation of rectifiers for railway service in the world was made on the city-owned subway system in New York City, between 1930 and 1940. The aggregate capacity of rectifiers on that system is about 330,000 kw. The rectifier units are rated at 3,000 kw, 625 volts, with 150 per cent of rated load current for two hours, 200 per cent for five minutes, and 300 per cent for one minute.

An interesting feature of the subway installations is that underground substations are used, located adjacent to the subway tracks. This effected considerable savings by obviating the purchase of substation sites in congested areas, and was possible because the ventilation problem was eliminated by using rectifiers. The rectifier transformers are also water cooled. A perspective drawing of an underground substation is shown in Figure 23. During installation, the equipment was lowered into the stations through openings from the street, which were then sealed off. There are also a few surface substations, with several rectifier units per station. The substations are automatically operated, with supervisory control and telemetering at a central dispatcher's office.

Delaware, Lackawanna and Western Electrification

Another interesting installation of rectifiers was made in 1930, for the 3,000-volt electrification of the suburban section of the Delaware, Lackawanna and Western Railroad, between Hoboken and Dover, N. J.[2] The 3,000-volt d-c power is supplied from five rectifier substations, with a total capacity of 39,000 kw. Two substations have four 3,000-kw units each, two substations have two 3,000-kw units each, and one substation has two 1,500-kw units. All rectifier units have a 12-phase connection and a Class III heavy-duty railway rating. The four larger substations are manually operated. The fifth substation is automatic, with supervisory control from the nearest attended substation. The substations are spaced from 7 to 15 miles apart.

Electrochemical Service[43]

Operating Conditions

In electrochemical service, the load circuit consists of many electrolytic cells connected in series. The same current flows through all the cells, and the voltage per cell is a characteristic of the electrolytic process. There is no solid ground on the circuit; however, there usually is a floating ground due to leakage current between cells which are at different potentials in the circuit. In some installations the mid-point of the circuit is grounded through a resistor.

Electrolytic cells are characterized by a counter-electromotive force and resistance. The counter-electromotive force voltage is between about 30 and 75 per cent of the applied voltage, at rated current, for the different electrolytic processes.[22] When the power supply is interrupted, the counter-electromotive force decreases gradually to zero. Some electrolytic circuits with a high counter-electromotive force will take a high inrush current when power is applied after the counter-electromotive force has dropped to a low value or zero. In some cases it is necessary to start at reduced voltage or with a resistor in series. The cell circuits also have inductance due to the loop traversed by the load current.

Rectifiers are used in electrochemical service for d-c operating voltages from 250 to about 800 volts. In most applications, however, the operating voltage is 500 volts or higher. The conversion equipment operates continually at about full load. In addition to the continuous rating, the equipment has a 150 per cent rating for one minute. The voltage regulation (that is, the drop in output voltage between no load and full load) of a rectifier unit is of no importance in electrochemical service, because the load current is constant. The rectifier transformers are designed usually with a high reactance, of the order of 8 to 10 per cent, in order to limit the magnitude of fault current during an arc-back.

The rectifier output voltage can be adjusted by phase control, to compensate for variations of the a-c supply voltage or for changes in the cell-line. A phase-control range of about 5 per cent is usually sufficient, although a larger range is used sometimes for short periods. In applications requiring a large range of voltage adjustment for continuous operation, the a-c voltage of the rectifier transformers is varied by a load tap-changing voltage regulator. If the change in the level of the operating voltage is made only at infrequent intervals, this can be done by taps on the rectifier transformer or an autotransformer, with a tap changer operated at no load.

Because of the high current ratings required, pumped rectifiers are used generally for electrochemical service. (Some sealed-tube units have been applied for electrochemical processes requiring relatively low currents). The rectifier station layout does not differ greatly from that of other applications. The equipment of each unit is arranged in sequence of the current

Table I. Estimated Capacity of Mercury-Arc Rectifiers Installed or on Order up to January 1, 1948

Application	United States, Kilowatts	Canada, Kilowatts
Electrochemical		
Aluminum	1,743,000	1,201,000
Chlorine	680,000	11,000
Magnesium	122,000	
Zinc	29,000	29,000
Hydrogen		61,000
Others	98,000	
Total	2,672,000	1,302,000
Railway		
600 volts	714,000	57,500
1,500 volts	42,000	3,000
3,000 volts	46,000	1,500
		(2,400 volts)
Total	802,000	62,000
Industrial	247,000	11,000
Mining	149,000	
Sub-totals	3,870,000	1,375,000
Grand total	5,245,000 kilowatts	

flow between the a-c and d-c busses. A basement, or low-headroom ground floor, is usually provided below the rectifier room, for the electrical interconnections between the component parts of the units, for the water piping, and the control wiring. Sometimes the cooling equipment and circuit breakers are also placed there.

The control cubicle, which contains the excitation and control equipment for the individual rectifiers, is placed next to the rectifier. The station is operated from a central control switchboard, on which are mounted the indicating instruments and the control switches for all the circuit breakers. A section of a typical rectifier station in an electrochemical plant is shown in Figure 24. The connection between the rectifier transformer and the negative bus is placed near the ceiling of the rectifier room, to increase the spacing between the positive and negative connections. This provides a higher inductance in the d-c circuit, which reduces the harmonic components in the direct current of the individual units.

Aluminum

The total installed capacity of rectifiers for aluminum production, in the United States and Canada, is about 3,000,000 kilowatts, which is nearly 60 per cent of all rectifier applications. The aluminum plant at Arvida, Canada, has the largest rectifier installation in the world in one location, with a total capacity of 747,000 kw. A typical aluminum cell-line or potline is supplied with a direct current of 55,000 to 60,000 amperes at about 650 volts. Most of the Canadian installations operate at 700 volts. The counter-electromotive force of the potline is about 30 per cent of the operating voltage. Approximately 10 kilowatt-hours of energy is required per pound of aluminum produced. The a-c power for the rectifier stations is obtained usually from hydroelectric power stations over high-voltage transmission lines. The voltage is stepped down to about 13 kv by transformer banks near the rectifier station.

A single-line power-circuit diagram of a typical rectifier installation for two aluminum potlines is shown in Figure 25.[15,19] Six 10,000-ampere rectifier units supply each potline. Each unit consists of two rectifiers connected to a rectifier transformer with two d-c windings, which have a 6-phase double-Y connection as shown in Figure 14. Each rectifier usually consists of 12 single-anode pumped tubes and is connected to its 6-phase transformer d-c winding through six anode-paralleling reactors and a 6-pole

Figure 23. Underground rectifier substation on New York City subway system

anode circuit breaker. The cathode terminal of each rectifier is connected to the positive d-c bus through a semi-high-speed d-c circuit breaker. The negative terminals are connected to the negative d-c bus through disconnecting switches.

Three of the rectifier transformers have delta-connected a-c windings, and three have Y-connected windings. By this combination and the 10-degree phase-shifting autotransformers on four units, a 36-phase rectifier system is obtained for the six units. This eliminates from the a-c line current the harmonic components which could cause interference in communication circuits.[1]

The rectifier units can be connected to either 3-phase a-c bus by means of air-break disconnects, which are capable of interrupting the magnetizing current of the rectifier transformers. Two a-c busses are used, to provide greater flexibility in supplying power for the two potlines and to insure continuity of service in case of accidental damage on one bus. Power to the a-c busses is supplied through a-c circuit breakers.

An arc-back in an individual rectifier is cleared by its anode circuit breaker, overload protection is provided by the d-c circuit breaker. The rectifier transformers and phase shifters are protected by overload relays, which are connected to current transformers on the individual units and trip the a-c line circuit breakers in case of a fault in a transformer or between a transformer and the anode circuit breakers. The relays do not operate during an arc-back.

There is no circuit breaker between the d-c bus and the potline circuit. To apply power to the potline following an outage, grid or excitation control of the rectifiers is utilized to make all the rectifiers of one potline start conducting simultaneously, after the circuit breakers have been closed. Power to a potline is interrupted by simultaneous tripping of the d-c circuit breakers of all the units supplying the potline. A tie circuit breaker is provided between the positive d-c busses of the two potlines. This tie is closed normally and aids in equalizing the load among the rectifier units, in case a rectifier should trip out or is taken out of service for maintenance. The tie circuit breaker is opened before power on a potline is switched off.

Auxiliary power transformers are installed to supply power for the excitation, vacuum pumps and cooling equipment of the rectifiers, and for other power requirements in the rectifier station. Each rectifier is cooled by a recirculating water system, with a water-to-water or a water-to-air heat exchanger. In many installations in the United States, water-to-air heat exchangers are used and are located on the roof of the rectifier building.

Another typical power-circuit diagram of a rectifier installation for an aluminum or magnesium plant is shown in Figure 26.[20] The connection of the rectifiers is the same as in Figure 25. However, in Figure 26 metal-clad, draw-out type a-c switchgear is used on the 13.8 kv circuit. A circuit breaker is used between each rectifier unit and the a-c bus, in addition to the anode circuit breakers. The 13.8 kv supply system is sectionalized, to limit the kilovolt-ampere interrupting capacity required for the circuit breakers. The auto-transformers shown in Figure 26 are required in some installations for reducing the d-c output voltage to a low value when starting a new cell-line.

Anode circuit breakers were not employed in the rectifier installations of the Canadian aluminum plants. An a-c circuit breaker was used between the a-c bus and each rectifier unit, and a high-speed d-c circuit breaker with reverse-current trip was used between each

rectifier and the positive d-c bus. This arrangement was employed also in the United States for the first rectifier installation in an aluminum plant.[18]

All the operating functions for the electrical equipment of two to four aluminum potlines are performed from one central switchboard. On this switchboard are mounted the indicating instruments, the control switches for the a-c line and rectifier circuit breakers, the voltage-control switches of the rectifiers, the control switches for the potlines, and other station controls.

A relatively small range of phase control is used for adjusting the d-c output voltage, usually less than 5 per cent. In some installations, where large variations in the a-c supply voltage occur, automatic load tap-changing voltage regulators are used for regulating the a-c bus voltage.

In Figure 27 is shown a view of a rectifier installation with 24 5,000-ampere rectifiers for two aluminum potlines. The anode circuit breakers are near the left wall. The rectifier control cubicles are at the right of the rectifiers, and the d-c circuit breakers are near the right wall. The d-c busses were located outdoors, outside of the right wall of the building. The water-to-air heat exchangers were on the roof of the building. Figure 28 shows a view of the a-c bus structure, rectifier transformers, and phase shifters in a rectifier installation for production of aluminum.

Magnesium[45]

Several large rectifier installations for production of magnesium were made during the war. Many of these rectifiers have since been transferred to other applications, mostly for production of chlorine and allied processes.

In so far as the power conversion equipment is concerned, a magnesium cell-line is similar to an aluminum potline, and the power-circuit diagram of Figure 26 is typical for this application also. A large magnesium cell-line operates normally with a direct current of 60,000 amperes at 600 volts. In one large magnesium plant built during the war, 20,000-ampere 350-volt cell-lines were used. A rectifier installation for a 60,000-ampere 600-volt magnesium cell-line is shown in Figure 29. The anode circuit breakers are at the left, and the control cubicles and d-c circuit breakers are at the right of the rectifiers.

The counter-electromotive force voltage of magnesium cells is approximately 35 per cent of the applied voltage. A wider adjustment of the voltage is required for a magnesium cell-line, because a new cell-line is started with only a few cells in series, and additional cells are added to the circuit over a period of several weeks. An autotransformer with load ratio control is used ahead of the a-c bus to provide the needed voltage range. Normally the cell-line operates at approximately full voltage.

Chlorine[20-43]

A typical chlorine cell-line operates with 7,500 to 10,000 amperes d-c at 500 to 700 volts, depending on the type of cell and the number of cells connected in series. However, there is a trend towards the use of higher-current cells. The counter-electromotive force of a chlorine cell is approximately 65 per cent of the applied voltage.

Usually each cell-line is supplied by one or two rectifier units, without paralleling with other cell-lines on the d-c side except in an emergency. Some cell-lines are designed for 1,800 to 2,000 amperes, and a number of these may be operated in parallel. A relatively small range of voltage control is required in normal operation, and is effected by phase control on the rectifiers. When starting a cell-line which has no counter-electromotive force, the voltage has to be reduced to about 30 or 40 per cent of normal for a short time, to limit the initial inrush current until the counter-electromotive force is established. Sometimes a resistor is connected in series with the cell-line on starting, to limit the inrush current.

A typical rectifier unit for a chlorine cell-line consists of two rectifiers connected to one transformer, similar to one of the units used in aluminum plants. The rectifier transformer is connected to the a-c circuit through an a-c circuit breaker. High-speed or semi-high-speed d-c circuit breakers are used between the rectifiers and the d-c bus. In the more recent installations, high-speed anode circuit breakers and semi-high-speed d-c circuit breakers are employed. Sometimes a single d-c circuit breaker is used for both rectifiers.

Zinc[30]

A typical zinc cell-line operates with 10,000 amperes direct-current at 500 or 600 volts. Each cell-line is supplied by one rectifier unit consisting of two rectifiers and one transformer, with an a-c circuit breaker and a high-speed d-c or anode circuit breaker. The counter-electromotive force of a zinc cell-line is about 75 per cent of the applied voltage.

A zinc cell has to be taken out of service periodically for stripping the zinc from the electrodes. To facilitate disconnecting the cell, the current of the circuit is reduced to a low value for a short time by reducing the voltage by about 25 per cent. A separate regulating transformer with load-tap-changing, or taps on the rectifier transformer, are used for reducing the voltage. When a cell-line is started with low or zero counter-electromotive force, the voltage is reduced to a low value by the regulating transformer and phase control on the rectifiers.

Because of the high counter-electromotive force of zinc cells, the ripple in the output voltage of a 6-phase rectifier will produce an appreciable ripple current. A reactor is connected in series with the rectifier to limit this current. A reactor is not required for a 12-phase rectifier.

Hydrogen[4]

A typical hydrogen cell-line operates with 10,000 amperes at 600 to 800 volts. Each cell-line is supplied by a separate rectifier unit, the same as for zinc cell-lines.

A water rheostat is connected in series with the cell-line on starting, to limit

Figure 24. Section through rectifier substation for electrochemical service

inrush current. The same rheostat is used when the cells are short-circuited for depolarizing.

Industrial Service

Applications

Mercury-arc rectifiers are used for supplying d-c power, at substantially constant voltage, in many types of industrial plants such as steel mills, foundries, smelters, paper mills, rubber plants, printing plants, metal fabricating plants, and others. The power is used for operating cranes, conveyors, electromagnets, ore and coal handling equipment, machine tools, and other motor-driven equipment using d-c motors.

Unit sizes between about 150 and 1500 kw are used, at various d-c output voltages between 125 and 600 volts. However, for most applications the operating voltages are between 240 and 275 volts. Rectifier units for industrial service have a rating of 125 per cent of rated load for two hours and 200 per cent for one minute, in addition to the continuous rating. The rectifier transformers are designed for a temperature rise of 60 degrees centigrade at the 2-hour rating.

When a 250-volt rectifier is applied on a 250/125 volt 3-wire d-c circuit, a balancer set is generally used to provide the middle wire. It consists of two 125-volt rotating d-c machines coupled mechanically and connected in series. The balancer set is connected in parallel with the rectifier, and the middle wire of the d-c circuit is connected to the junction point between the two machines of the balancer. The current of the balancer is one-half the current of the middle wire. Instead of using a balancer, a 3-wire circuit can be obtained with rectifiers. However, such a circuit consists essentially of two 125-volt rectifiers in series, which would have a poor efficiency.[28]

While most of the rectifiers in industrial service are for constant output voltage, some rectifiers with a wide range of voltage control have been installed for specific motor drives. The voltage is reduced to a low value for starting the motors, but a smaller range of voltage control is needed in normal operation. So far, rectifiers have not been applied for reversing-mill drives, because the need for regeneration and the desirability of using stored flywheel energy for supplying the recurrent high load peaks make motor-generators more favorable.

Rectifier Units

Sealed-tube rectifiers are used generally for unit ratings below 600 kw. Pumped-tube rectifiers are usually applied for higher ratings. The rectifier circuit of Figure 14 is used for most applications. Some small sealed-tube units were supplied with a 4-phase connection, obtained by using a Scott-connected transformer a-c winding. For most industrial applications, a-c and d-c circuit breakers are employed for switching and protection.

The tubes of pumped rectifiers are assembled on a frame with the evacuating equipment, as for other applications. In most plants the a-c circuit breakers and rectifier transformers are placed indoors. It is the usual practice to have the a-c and d-c circuit breakers mounted in metal-enclosed cubicles. In Figure 30 is shown a 1,500-kw pumped rectifier installed in a steel mill.

Sealed-tube rectifier units are supplied as factory-built unit-type substations, with the rectifier equipment and circuit breakers mounted in metal-enclosed cubicles. In Figure 31 is shown a 500-kw unit with 12 sealed tubes. The sequence of the equipment from left to right is: a-c switchgear cubicles, rectifier transformer, tube cubicles, control and d-c circuit breaker cubicles, and d-c feeder circuit breaker cubicles (not shown). The rectifier tubes are seen through the open door of one of the tube cubicles. In Figure 32 is shown a sealed-tube unit with six 400-ampere tubes. The rectifier excitation equipment and the cooling-water connections are contained in the tube cubicle. The voltage regulator and other controls are usually mounted in the d-c circuit breaker cubicle. The tubes are cooled by raw water or by a recirculating system with a heat exchanger.

Figure 25. Typical single-line power-circuit diagram of rectifier installation for two potlines in aluminum-production plant

Controls

Rectifier units in industrial service are started and stopped manually, but otherwise are usually unattended. They are provided with d-c voltage regulators for maintaining constant output voltage, or some other desired voltage characteristic, by phase control. Two or more rectifiers may be operated in parallel by means of current-equalizing connections on the voltage regulators, or by current compounding to give the rectifiers a slightly drooping voltage-regulation characteristic. Rectifiers can be operated in parallel with rotating machines by matching their voltage characteristics.

When a rectifier is used to supply power to cranes or elevators which require regenerative braking, the regenerated power has to be absorbed by other loads connected to the d-c circuit, because reverse current cannot flow into the rectifier. If there is not sufficient other load to absorb this power, an automatically-controlled dynamic braking resistor is provided. The resistor is connected to the d-c bus by an overvoltage relay and a contactor whenever the d-c voltage generated by the motor with the overhauling load rises above a preset value. The resistor is disconnected automatically after a preset time. If regeneration persists, the cycle is repeated.

Mining Service

Rating

During the last decade approximately 400 mercury-arc rectifier units with a total capacity of about 150,000 kw, were sold in the United States for mining service, most of them for coal mines.[13] A large majority of them are portable sealed-

Figure 26. Typical single-line power-circuit diagram of rectifier installation for aluminum or magnesium production, using metal-clad, drawout type a-c switchgear

Figure 27. View of rectifier installation in aluminum-production plant

Twenty-four 5,000-ampere rectifiers are shown, for supplying two 650-volt potlines

tube units for ratings of 200 to 500 kw, with a d-c output voltage of 275 volts. In some installations the output voltage is 575.

Rectifier units in mine service generally have Class I railway rating, with 150 per cent of the continuous rating for two hours and 200 per cent for one minute. The load consists mostly of electric locomotives, pumps, cutters, drillers, and loading machines. Where a rectifier substation is located along the main haulage way, and the load consists largely of locomotives, Class II railway rating is used sometimes, with a 1-minute rating of 300 per cent.

Units

Stationary rectifier units are installed in surface substations, and are similar to units built for other applications. Portable underground units are mounted on low-headroom cars, with an over-all height of 42 to 52 inches above the rails. A typical portable substation is shown in Figure 33. It consists of three cars. The first car on the left contains the a-c switchgear and the auxiliary-power transformer. On the second car is mounted the rectifier transformer. The third car contains the rectifier tubes with their excitation and cooling equipments, the d-c switchgear, and the control panel. The rectifier is cooled by a recirculating cooling system with a water-to-air heat exchanger. For safety reasons, the sides of the cars are enclosed by covers so that no live parts are exposed.

This type of unit can be moved easily to new locations, close to the load center, as mine operations progress. It is placed on a siding in the mine tunnel, and the only external connections are the a-c supply leads and the outgoing d-c leads. One of the d-c terminals is grounded.[42]

Control

Most of the rectifier units in mining service are semiautomatic. The unit is started and shut down by a pushbutton, but operates automatically after it is started. The a-c and d-c circuit breakers reclose automatically if they are tripped by overload or a fault. The d-c circuit breaker serves also as a feeder circuit breaker and is provided with load-measuring controls. This control feels out the load through a bridging resistor across the open circuit breaker and closes only if the load is not excessive. A voltage regulator is provided to maintain the output voltage substantially constant up to full load, by phase control.

Operation

Rectifiers were adopted for mining service for the same reasons as in other applications: high all-day efficiency, low maintenance cost, simplicity of control and operation. A comparative efficiency test made on a rectifier, a synchronous converter, and a motor-generator set, over a period of one month, in a coal mine operating at 275 volts with a load factor of approximately 25 per cent, gave the following results: rectifier, 84 per cent efficiency; synchronous converter, 77 per cent efficiency; motor-generator, 69 per cent efficiency.

Variable-Speed Motor Drives

Application

Induction motors are used for the majority of industrial applications, because of their simple construction and the advantages of 3-phase a-c power distribution. However, d-c motors are required for many variable-speed drives. The need for adjustable-speed d-c drives is growing because of the high standard of performance required in some modern industrial operations. Where d-c power is available, d-c motors can be applied readily when a limited speed range, obtainable by field control, is needed. Where only a-c power is available, an a-c to d-c converter must be used for operating d-c motors. For motor drives with a wide range of speed control, or where regenerative braking and reversing is required, motor-generator sets with Ward-Leonard control are generally used.

About ten years ago, single-phase thyratron-tube rectifiers, with variable output voltage by phase control, were first used for supplying adjustable-speed d-c motors from an a-c system. This type of motor drive has found application in sizes of 1 to 15 horsepower and is used also where regenerative braking and re-

Figure 28. View of a-c b s structure, rectifier transformers, and phase shifters in aluminum - production plant

versing is required. The application of electronic d-c motor drives has been extended recently to motor sizes in the range of 100 to 600 horsepower, by using sealed-tube pool-cathode mercury-arc rectifiers. These applications are made preferably with 550-volt motors and where reversing is not required. More than a score of applications have been made for printing press drives, with rectifiers rated between 150 and 300 kw. The electronic drive provides for complete control including starting, jogging, low-speed running, acceleration, and emergency stopping.

Several applications have been made also with large pumped rectifiers for adjustable-speed main motor drives in steel mills, including a 3,500-kw rectifier for a continuous tube mill. The rectifier is designed for continuous operation with 40 per cent voltage reduction by phase control and with 95 per cent reduction for starting. The use of phase control lowers the power factor of the rectifier unit by about the same ratio as the voltage reduction. When a large reduction in voltage is required for continuous operation, it is preferable to obtain the reduction by taps on the rectifier transformer.

Connection Diagram

An elementary diagram of an electronic d-c motor drive with a sealed-tube rectifier is shown in Figure 34. A 6-phase double-way rectifier connection is used, which provides the required output voltage for a 550-volt motor when connected to a 3-phase 460-volt a-c supply. When the a-c supply voltage is higher, the voltage required for the rectifier is obtained by means of a step-down transformer.

By using a 6-phase rectifier, the distortion of the direct current due to the ripple in the rectifier output voltage is minimized, and a d-c motor approximating conventional design can be used.

Current-limiting reactors are connected to the a-c circuit, for protection of the tubes against excessive fault currents in case of an arc-back in the rectifier or a d-c short circuit. The auxiliary power required for the rectifier excitation and controls is supplied from the a-c circuit. The excitation circuits of rectifiers and the methods of retarding the firing of the anodes for phase-control of the output voltage were described in Part II. The rectifier tubes with their auxiliaries, and all the switching and control equipment are mounted and wired in metal-enclosed cubicles similar to a unit-type substation.

Controls

The acceleration and speed of the motor are controlled automatically. The rate of acceleration and the desired speed are set manually by means of adjustable controls. Phase-control of the rectifier output voltage, from zero to 100 per cent, is used for acceleration of the drive from standstill to the required speed. The rate of acceleration is controlled by current-limit control, which does not permit the armature current to rise above a predetermined value. This method provides smooth acceleration for various motor loads and prevents overloading the equipment and supply circuit.

After the a-c circuit breaker is closed and the control is energized, the motor can be started from rest by turning the speed-control potentiometer to the desired speed setting. During acceleration to base speed (see Figure 35), full field excitation is supplied to the motor from a separate source, and the armature current is controlled automatically by phase control of the rectifier. When base speed is reached, the rectifier output voltage is a maximum, and higher speeds are attained by weakening the motor field.

When the motor has reached the speed corresponding to the speed-dial setting, it will run continuously at that speed independent of the motor load, provided the armature current does not exceed the preset limit. When the speed dial is turned to a lower setting, the motor will be decelerated by its load until the desired lower speed is reached, which is then maintained automatically.

Because reverse current normally cannot flow into a rectifier, dynamic braking of the motor by regeneration is not possible unless the rectifier is made to operate as a power inverter and the armature or field connections are reversed, which would complicate the controls considerably. A dynamic-braking resistor is provided for rapid deceleration of the motor or emergency stopping. When the "emergency-stop" button is operated, the motor is disconnected from the supply circuit and the dynamic-braking contactor is closed.

Characteristics

The calculated performance characteristics of a typical electronic 150-horsepower motor drive, for a printing press or other applications, are given in Figure 35. Good efficiency and power factor are obtained in the running speed range, where the power required is high, by operating the rectifier without phase control and regulating the motor speed by field control. These characteristics drop off at lower speeds, where the power requirements are reduced, because the rectifier output voltage is reduced by phase control. The arc-drop voltage of the rectifying elements is the major rectifier loss; it becomes a larger percentage of the reduced output voltage at low speeds and therefore lowers the efficiency.

For some types of motor load, the use of field control for speed regulation in the running range will result in a larger motor. This has to be balanced against the lower efficiency and power factor if the whole range of speed adjustment were accomplished by rectifier phase control.

Other Rectifier Applications

Power for R-F Oscillators

High-voltage mercury-arc rectifiers have been applied for supplying plate power to radio-frequency oscillators.[6] Several such installations have been made in North America, in radio transmitting stations and for testing high-power trans-

Figure 29. View of rectifier installation in magnesium-production plant

Twelve 5,000-ampere rectifiers supply a 600-volt cell-line

mitter tubes. The first installation was made in 1933, in a radio broadcasting station in Mexico. Units with ratings from 200 to 1,000 kw have been supplied for d-c output voltages between about 10 and 20 kv.

An a-c circuit breaker for connecting the rectifier unit to the a-c supply circuit is the only circuit breaker used. No d-c or anode circuit breakers are available for these voltages. The rectifier transformers of pumped high-voltage rectifiers have a d-c winding with a 6-phase star or fork connection. For sealed-tube rectifiers, the 6-phase double-way connection is preferred.[37] A series reactor and a shunt capacitor usually are connected to the d-c circuit for filtering the d-c output voltage.

An important feature of rectifiers for this application is the use of arc suppression, by means of grid or firing control, for interrupting short circuits in the load circuit and arc-backs in the rectifier, without tripping the circuit breaker. This protection interrupts the fault in one to two cycles and resets automatically to restore normal voltage in a fraction of a second. With this high-speed protection, transmitter tubes are saved from damage in case of internal flashover, and longer tube life is obtained. The quick restoration of power following a fault prevents interruption of service, an important consideration in radio broadcasting.

Mercury-arc rectifiers can be used for supplying high-power radio-frequency oscillators for induction and dielectric heating. In addition to the benefits of high-speed protection, the grid or firing control can be used for switching the power on and off, and for regulating the power output by phase control of the rectifier voltage.

Electronic Exciters

Sealed-tube mercury-arc rectifiers have been applied for field excitation of large synchronous condensers and turbine generators. The first application on a synchronous condenser was made in 1939, and several other installations have been made since then.[41] The first application on a large generator was made about two years ago.[84] A high degree of reliability is required for this service, and the rectifiers are designed so that arc-backs are cleared or tube replacements made without shutting down the generator.

A typical rectifier for this application consists of six tubes, which are connected through anode circuit breakers to a 6-phase star- or fork-connected d-c winding of a rectifier transformer. In synchronous condenser installations, the rectifier unit is supplied from the a-c system. When used for generator excitation, the rectifier unit may be supplied from the generator terminals or from the station auxiliary bus. On one application the generator was provided with a direct-connected 6-phase auxiliary a-c generator for supplying the rectifier tubes.

The equipment of the rectifier unit is mounted in metal-enclosed cubicles. Each pair of tubes, which are connected to diametrically opposite phases, with their excitation equipment and a 2-pole anode circuit breaker, are mounted in a separate cubicle compartment. To replace a tube, the corresponding anode circuit breaker is opened while the remaining four tubes continue to operate. During an arc-back the anode circuit breaker of the faulted tube trips and recloses automatically.

During a fault on the a-c system, the field excitation of the synchronous machine must be increased. To take care of this requirement and to compensate for a drop in voltage on the a-c circuit to which the rectifier is connected, the rectifier unit is designed for a considerably higher output voltage than required in normal operation. It therefore operates normally with a large amount of phase control. This provides sufficient voltage margin in normal operation even when two tubes are disconnected by an arc-back or for maintenance. The output voltage of the rectifier is regulated usually by the voltage regulator of the synchronous machine.

A relatively small number of electronic exciters of this type have been applied so far. Its advantages over d-c generator exciters are that it has a faster response, is stationary and has no commutator. Its reliability has been demonstrated in service. However, it is considerably more expensive and involves more equipment and more elaborate circuits.

Electronic Switches

Pool-cathode mercury-arc rectifier tubes are used also as switches. They are superior to mechanical contactors, because they have no moving parts, can be controlled easily and with precise timing, can handle high currents, and are completely enclosed. Their chief use as switches is for resistance welding control, with two tubes connected back to back for 2-way conductivity in the a-c supply circuit to the welding transformer. They have been applied also for discharging the stored energy of capacitors through the field coils of particle accelerators. In some of the power-converter applications, described in the preceding sections, the tubes perform switching operations in addition to their normal duty of power conversion. The difference between the two functions is that when operating as switches the flow of current in the power circuit is started or stopped, while in conversion of power the current is transferred from one part of the circuit to another in cyclic sequence.

The unit is rated at 1,500 kw and consists of 12 pumped tubes

Part VI. Power Inverters and Frequency Changers

Power Inverter

In Part V were discussed the various applications of mercury-arc rectifiers for conversion of a-c power to d-c power. A rectifier unit used for that purpose is called a power rectifier. A rectifier unit can be used also for converting d-c power to a-c power, and when used for that purpose is called a power inverter.

Principle of Operation

The power circuit of the unit and the direction of current are the same for either operating condition. The direction of power flow between the a-c and d-c circuits is determined solely by the part of the cycle of the phase voltages during which the anode currents flow. In a power rectifier the currents flow during the positive half-cycles; the d-c voltage, which consists of portions of the phase voltages during their conducting periods, is then in the same direction as the direct current, and power flows from the a-c circuit into the d-c circuit. When operating as a power inverter, the anode currents are made to flow during the negative half-cycles of the phase voltages. The rectifier d-c voltage is then in the opposite direction from the current, and power flows from the d-c circuit into the a-c circuit (see Appendix).

Figure 31. Sealed-tube rectifier unit, rated at 500 kw, for industrial service

Twelve 200-ampere tubes are used

To make current flow through the rectifier in the normal direction, from anodes to cathodes, during the negative half-cycles of the phase voltages, the positive terminal of the d-c supply circuit is connected to the terminal of the rectifier unit at which the direct current enters. This is the reverse of the connection of a power rectifier to a d-c load circuit. The voltage of the d-c supply circuit overcomes the negative voltage of the rectifier unit and causes a flow of current. The negative voltage of the rectifier unit, when operating as a power inverter, has the same function as the back-electromotive force of a d-c motor. The analogy can be carried further if the d-c motor is assumed to drive an a-c generator for delivering power into an a-c system.

A rectifier is made to operate as a power inverter by extension of phase control into the negative half-cycles of the phase voltages. By grid or ignition control of the rectifying elements, they are kept from firing during the positive half-cycles and are made conductive at some chosen point of the negative half-cycles. This is explained with the aid of sine waves in the Appendix. For some types of transformer connections, the rectifying elements are made conductive at the latter part of the positive half-cycles, but carry over far enough into the negative half-cycles so that the average voltage is negative.

Operating Conditions

In a power inverter the current is commutated between successive phases in the same way as in a power rectifier. The rectifier transformer must be provided with alternating voltages to effect the commutation. The voltages are obtained from the a-c system, and a power inverter can operate only when connected to an a-c system which has synchronous machines, or an oscillating circuit consisting of capacitance and inductance, for generating the needed voltages.

There is one other essential condition for the operation of a power inverter. For proper commutation the center line of each phase current, or the crest of the fundamental component of the current, must come before the negative crest of the corresponding phase voltage. This means that the output current of the inverter into the a-c line leads the output voltage; that is, the inverter operates with a leading power factor. As viewed from the a-c system, the inverter requires lagging reactive kilovolt-amperes, and the a-c system must have a source of such kilovolt-amperes. This can be provided by over-excited synchronous machines. If there is insufficient synchronous capacity on the system for that purpose, a synchronous condenser or static capacitors can be used. A power inverter can operate with a power factor of approximately 85 per cent at full load, so that the reactive kilovolt-ampere is about 65 per cent of the kilowatt output.

Characteristics

The efficiency of a power inverter is the ratio of the a-c power output to the power output plus the losses. The losses in the rectifier transformer, rectifier and auxiliaries are substantially the same as for a power rectifier designed for the same a-c and d-c voltages and for operation with about 10 per cent phase control.

In considering the voltage regulation of a power inverter which is connected to a large a-c system, it can be assumed that the a-c line voltage remains constant at all inverter loads. The voltage regulation is the change in the required d-c supply voltage between no load and full load on the inverter, while operating with a fixed phase-control angle. A higher d-c supply voltage is required at full load than at no load, to compensate for the voltage drop due to the reactance and resistance of the transformer. This voltage drop increases linearly with load and has the same value as for a power rectifier operating with the same transformer. The regulation characteristic for a power inverter is therefore a straight line sloping upward with load, instead of downward as for a power rectifier.

Faults

In a power rectifier, the anode of a rectifying element is negative to the cathode during the greater part of the nonconducting period of each cycle. The major fault in a power rectifier is an arc-back, which is the loss of rectifying action during the inverse period, resulting in a reverse current to the faulted anode. In a power inverter, the anode of a rectifying element is positive to the cathode during the greater part of the nonconducting period of each cycle. The major fault in a power inverter is an arc-through, which is a loss of control causing an anode to start conducting in the forward direction during its positive nonconducting period. The result is that the back-electromotive force of the inverter disappears, and the d-c supply is short-circuited over the faulted rectifying element and its transformer phase. The ultimate fault current is limited only by the resistance of the short-circuit path and the regulation of the d-c supply circuit. If not interrupted quickly, the current will reach a high value, comparable to the reverse current during an arc-back in a power rectifier.

Figure 32. Installation of sealed-tube rectifier unit, with six 400-ampere tubes

An arc-through can be interrupted by removing the d-c power supply. Under some conditions an arc-through can recover itself, without removing the d-c supply, if the fault current has not reached a high value when the next phase of the transformer starts conducting and is able to commutate the current away from the faulted phase.

Applications

Power inverters have been applied in electronic frequency changers, which are discussed in the next section. They can be applied also for regenerative braking on d-c railroad electrification in mountainous territory, and are used for that purpose in South Africa and Europe.

Electronic Frequency Changers

Frequency changers are used to convert a-c power of one frequency to a-c power of another frequency. Two types of electronic frequency changers employing

mercury-arc rectifiers are in use. In one type, power from an a-c system of one frequency is converted to d-c by a power rectifier; the d-c power is then converted to a-c power of another frequency by means of a power inverter. The d-c circuit serves as a link between the two a-c systems (Figure 44). This type is used for interconnection of power systems. In another type of frequency changer, the power rectification and inversion take place in the same rectifying elements, and there is no distinct d-c power link (Figure 39). This type is used for producing high-frequency power for induction heating of metals. The application and operation of both types will be described.

The power transmitted by an electronic frequency changer with a d-c link can be controlled by phase control of the power rectifier or the power inverter, or both. Advancing the firing of the anodes of the power rectifier increases its d-c output voltage and the transmitted power. Advancing the anode firing of the power inverter reduces its back-electromotive force and consequently increases the transmitted power. No power will flow if the output voltage of the power rectifier is lower than the back-electromotive force of the inverter.

The direction of power flow can be reversed by shifting the phase position of the firing-controls (grid or ignition control) on the two rectifiers, from one part of the cycle of the phase voltages to another part.

No change is necessary in the power circuit connections. The firing-control circuit of each rectifier unit is supplied from the a-c system to which it is connected.

Interconnection of Power Systems

Carnegie-Illinois Installations

In 1943, the Carnegie-Illinois Steel Corporation put into operation two electronic frequency changer installations for interconnecting the 25-cycle and 60-cycle power systems in steel mills. A 20,000-kw frequency changer was installed in the Edgar Thompson plant, near Pittsburgh, Pa. A 6,667-kw unit was installed in the Gary, Ind., plant. The latter installation will be enlarged soon to 16,000 kw.

In both plants, all the power of the 25-cycle system is generated by company-owned generating equipment. The 60-cycle power system is connected to a large public-utility system. The frequency changers are utilized to transmit power between the two systems, in either direction, depending on power requirements and availability on each.

Electronic frequency changers were chosen for this service, because the 25-cycle and 60-cycle power systems do not have a fixed frequency ratio, and it was desired to regulate the transmitted power independently of voltage or frequency variations on either system. For these reasons synchronous-synchronous frequency changers could not be used. Other types of rotating machines were considered, including the Scherbius induction-synchronous converter, two rotary converters, and two a-c/d-c motor-generator sets.

The electronic frequency changer was decided upon, in spite of its higher first cost and the pioneering involved, for the following reasons: higher efficiency at all loads; ease of power flow control; ease of starting, with no starting shock on the systems and without synchronizing; absence of large rotating parts, slip rings, commutators and brushes; lower installation cost; anticipated lower maintenance cost.

The good performance of these installations has justified the decision, and credit is due to those who undertook the pioneering risk. There was sufficient synchronous capacity on both systems in these installations to supply the reactive kilovolt-ampere requirements of the power inverters.

Before describing the electronic frequency changers of the two Carnegie installations, the general application and limitations of this type of equipment will be discussed briefly.

Application[54,55]

In general, a mercury-arc electronic frequency changer can be applied economically for interconnecting two power systems, under the following conditions:

1. Where a rigid frequency relation between the systems does not exist and cannot be established by a synchronous-synchronous frequency changer of the size considered.
2. The power receiving system has a synchronous generator or other synchronous machine, such as a synchronous condenser, and enough surplus capacity of reactive kilovolt-amperes for the inverter.

Where these conditions exist, as in the steel plants mentioned, the electronic frequency changer is not only more economical than a rotating machine but is also simpler to operate and has greater flexibility. However, the opportunities for such applications are few. New loads and generating equipment in steel mills usually are for 60 cycles.

For single-phase railroad electrification, where 25-cycle power is used, much of the power is supplied by 60/25 cycle frequency changers. However, they usually are installed in locations where condition 2 does not exist. An electronic frequency changer would require a 25-cycle synchronous condenser, which would probably make it uneconomical and would cancel other advantages realized in the Carnegie installations. In cities where 25-cycle systems are still in use, synchronous-synchronous frequency changers are generally employed for interconnecting the 60- and 25-cycle systems.

Electronic frequency changers would provide an excellent nonsynchronous tie between 60-cycle systems which cannot be operated in synchronism. If the interconnection points should be located far apart, the d-c link of the frequency changer could be stretched into a d-c transmission line, operating at a suitable voltage depending on the distance. Such an interconnection would be determined mainly by economic considerations.

Gary Frequency Changer[55]

Power Systems

The 6,667-kw electronic frequency changer was installed in the Gary, Ind.,

Figure 33. Portable rectifier substation for underground mine service

plant of the Carnegie-Illinois Steel Corporation, early in 1943, for interconnecting the 60-cycle and the 25-cycle power systems. All the power on the 25-cycle system is generated in United States Steel Corporation plants in the Chicago area, and a 66-kv transmission line connects the Gary and South Chicago plants. The 60-cycle system is furnished with power from the Northern Indiana Public Service Company, over 132-kv lines, and the voltage is stepped down to 6.9 kv for distribution in the plant. Each system has over 200,000 kw generating capacity. The frequency variation on the 25-cycle system is ±1.5 cycles, while the frequency on the 60-cycle system is maintained within ±0.1 cycle. This ruled out a synchronous-synchronous frequency changer.

The frequency changer is used for transfer of power between the two systems, in either direction, depending on power requirements. However, the installation was made primarily for supplying power from the 25-cycle system to the 60-cycle system, in order to control the demand on the 60-cycle power system and to increase the ratio of average power to maximum demand.

The original installation was furnished with pumped-type multianode mercury-arc rectifiers. These will be replaced in the near future with pumped single-anode excitron rectifiers, similar to the type shown in Figure 10, to increase the continuous rating of the unit to 8,000 kw with a 2-hour rating of 10,000 kw. A second 8,000-kw unit is on order, to double the capacity of the installation.

Figure 34. Elementary diagram of adjustable-speed, electronic d-c motor drive

Connection Diagram

A single-line power circuit diagram of the Gary frequency changer is shown in Figure 36. It consists of a 25-cycle and a 60-cycle rectifier units, which are connected to the respective a-c systems through oil circuit breakers. The d-c circuits of the two units are connected in series, so that the direct current flows through the rectifiers in the normal direction, from anode to cathode.

Each rectifier unit consists of a rectifier transformer and two 12-anode rectifiers, which are provided with two control grids per anode. The 25-cycle transformer is connected in delta/6-phase double-Y. The 60-cycle transformer is connected in delta/12-phase quadruple zig-zag. The rectifier transformers of the second 8,000-kw frequency changer will have their voltages shifted in phase in relation to those of the existing unit, so as to produce for the entire installation a 24-phase line current on the 60-cycle side and a 12-phase line current on the 25-cycle side. A larger number of phases is used on the 60-cycle side, because it is connected to a large public utility system and there is a greater likelihood of inductive influence on communication circuits.

The frequency changer consists of two sections, *A* and *B*, each of which can operate independently of the other. One section can be shut down for maintenance work while the other remains in operation. Such an arrangement is particularly desirable in this installation, because the frequency changer is used for controlling the maximum power demand averaged over 30-minute periods. Individual rectifiers can be isolated for maintenance work by means of disconnects.

Each section consists of a d-c winding of each transformer and the rectifiers connected to them. Considering section *A*, for example, when power is transmitted from the 25-cycle system to the 60-cycle system, 25-cycle power is converted to direct-current at 1,750 volts by means of rectifier *25-A* operating as a power rectifier, and the d-c power is converted to a-c power into the 60-cycle system by rectifier *60-A* operating as a power inverter. For power flow in the opposite direction, rectifier *60-A* operates as a power rectifier and *25-A* as a power inverter. The power circuit of the frequency changer and the direction of current in the d-c circuit remain unchanged for either direction of power flow. The direction of power flow is established by grid control of the rectifiers, which determines the position of the conducting period of each anode in the cycle of the a-c voltage applied to it (see Appendix).

The power transmitted by the frequency changer is controlled by means of a current regulator for each section, which regulates the magnitude of the current in the d-c circuit. The regulation is effected by phase control of the power rectifier, through grid control. The direct current of each section is maintained at a value corresponding to the setting of the regulator, regardless of voltage variations on the a-c power systems. The setting of the regulators can be adjusted either manually, or automatically in response to power demand.

Each section of the frequency changer is provided with a reactor and a circuit breaker in the d-c circuit. One purpose of the reactor is to reduce the ripple in the direct current and thus permit the frequency changer to operate at light load without discontinuities in the current wave. Another purpose is to reduce the rate of change of the current during a sudden large change in the a-c voltage, or during a fault on the inverters, thereby aiding the load regulators and the protection system.

Protection

Protection is provided against arc-backs in the power rectifier and arc-throughs in the power inverter, for either direction of power flow. Protection in the event of arc-back is provided by grid blocking (arc suppression) of the power rectifier, with tripping of the a-c circuit breakers as back-up protection. Grid blocking is effected by means of an electronic relay, which causes the application of a sustained negative voltage to the control grids. The arc-back is extinguished when the current of the anodes which fire to the faulted anode has dropped to zero.

An arc-through on the power inverter can recover itself within one cycle by

recommutation of the faulted anode by the succeeding anode, provided the fault current is below the commutation-limit value. Due to the action of the d-c reactor in reducing the rate of rise of current, most arc-throughs on the frequency changer are self-recovered, without operation of the protective equipment. Others are suppressed by grid-blocking of the power rectifier, without tripping of any circuit breaker. The grid-blocking circuit resets automatically in a fraction of a second, and the unit resumes normal operation. If the cause of the arc-through persists, such as a sustained fault on the grid-control circuit or a loss of voltage on the a-c system to which the power inverter is connected, the fault is cleared by automatic tripping of the d-c circuit breaker. The protective equipment operates only on the section of the frequency changer on which the arc-through occurs. Back-up protection is provided by the a-c circuit breakers, which are tripped by overload relays. The trip coils of the a-c circuit breakers are connected in parallel, so that operation of the overload relays on either side will trip both circuit breakers. Arc-back and arc-through protection of excitron rectifiers can be effected either by grid blocking or by interrupting the excitation arcs.

Installation and Operation

The a-c circuit breakers, the rectifier transformers, and the d-c reactors are located outdoors. The rectifiers with their auxiliaries, the d-c circuit breakers, and the control equipment are indoors. Each rectifier is cooled by a separate recirculating water cooling system, with a water-to-water heat exchanger. A control cubicle is provided for each rectifier. The indicating and recording instruments, the load regulators, the control switches for the circuit breakers, and the overload relays for the a-c circuit breakers are mounted on a station control switchboard.

The frequency changer operates with the cathodes of the power rectifiers grounded, irrespective of the direction of power flow. This makes it possible to mount the current-regulating and grid-blocking equipment without special insulation from ground. The change in direction of power flow is effected by means of double-throw switches in the rectifier control cubicles. These switches change the phase position of the grid-control voltages in relation to the anode voltages, and connect the load-regulating and grid-blocking circuits to the power rectifiers.

During an experimental period following the installation of the frequency changer, there were frequent outages. As a result of improvements in the rectifiers and the grid-control and load-regulating circuits, the performance during the last several years has been good. Outages are infrequent. Several arc-throughs per day occur on the power inverter, but are suppressed without tripping any circuit breakers. In case of an outage, the unit is returned to service immediately.

The efficiency of the frequency changer is approximately 93 per cent at full load, and the curve is fairly flat over the greater part of the load range. The power factor on the inverter side at full load is between about 82 and 84 per cent, depending on the direction of power flow. On the power supply side, the power factor is between about 85 and 95 per cent at full load, depending on the amount of phase control required by the power rectifier for load regulation.

Edgar Thompson Frequency Changer[35,36]

Power Systems

The 20,000-kw electronic frequency changer operating at the Edgar Thompson works of the Carnegie-Illinois Steel Corporation, near Pittsburgh, Pa., was placed in commercial service in December, 1943. Power may be exchanged in either direction between the steel company's 69-kv 60-cycle system, which is connected to a public utility, and their 44-kv 25-cycle system. The generation capacity of the 60-cycle system exceeds 600,000 kw, and the 25-cycle system has over 125,000 kw. The two power systems do not have a fixed frequency ratio; and they are both so large that a synchronous-synchronous rotating converter having the necessary torque to hold them in step would be prohibitive.

Power Circuit

The main power circuit diagram, Figure 37, shows that the electronic frequency changer has the following features:

1. There are two separately-operable 10,000 kw units, each consisting of two sections.

2. The frequency changer circuit has a d-c link, involving distinct power rectification, d-c interconnections and power inversion.

3. Sealed pentode ignitron tubes (Figure 6) were used,[32] which permitted the use of a double-way transformer circuit. Such a rectifier transformer is simpler and physically smaller than a single-way transformer.[27] If pumped ignitrons were used, they would have required transformers with single-way connection of the d-c windings, because their cathodes are interconnected by the vacuum pumps.

4. Both 60- and 25-cycle transformers have delta and wye a-c windings, so combined with zig-zag connected d-c windings, that an over-all 24-phase system is obtained. Current-limiting reactors are connected in series with each d-c winding, for limiting the fault current during an arc-back or an arc-through. The reactors are installed in the transformer tanks.

The frequency changer consists of several duplicate rectifier groups. When power flows from the 60-cycle to the 25-cycle system, the rectifying elements on the 60-cycle side operate as power rectifiers, converting a-c power to direct-current at 12,500 volts. The rectifying elements on the 25-cycle side operate as power inverters, converting the d-c power to a-c power into the 25-cycle system. Conversely, when the direction of power flow

Figure 35. Characteristics of adjustable-speed, electronic d-c motor drive

Figure 36. Power-circuit diagram of electronic frequency changer installed in Gary steel mill

is from the 25- to the 60-cycle system, the 25-cycle rectifying elements operate as power rectifiers and the 60-cycle units as power inverters.

Power Control

The installation is designed for unattended operation, although an observer is usually present in the building. It is controlled from remote panels located in a 60-cycle power station several hundred feet away. The operator can close the main a-c circuit breakers to place the frequency changer in service, and can select one of several methods of power control, as follows:

1. Power flow continually in either direction.
2. Adjust the rate of power flow, which will be maintained automatically at the set value.
3. Set the frequency changer to maintain automatically a desired rate of purchased 60-cycle power, within limits. This may involve automatic reversal of power flow direction, depending on generation and consumption of 60-cycle power within the company's own 60-cycle system.

The direction of power flow is established by the phase position of the supply voltages to the ignition and grid-control circuits, in relation to the transformer phase voltages of each rectifier. The change from one direction to the other is accomplished by means of contactors, operated by a master control.

The power transmitted by the frequency changer is regulated by phase control on both, the power rectifiers and the power inverters. The phase control is adjusted by means of saturable reactors in a phase-shifting network, which supplies the ignition and grid-control circuits of each rectifier group. An amplidyne, controlled by the power regulator, supplies a variable direct current to the magnetizing windings of the saturable reactors. Each rectifier group is provided with a phase-shifting network and an amplidyne. The voltages for the ignition and grid circuits of individual tubes in each group are obtained from the phase-shifting network through insulating transformers, because the tubes are insulated from each other.

Protection

Arc-backs in the power rectifier and arc-throughs in the power inverters are interrupted by arc suppression, through grid and ignition controls, without tripping the a-c circuit breakers.

When a fault occurs, instantaneously-operated thyratron tubes and backup relays block the conductivity in all the ignitron tubes of the 10,000-kw unit involved, by stopping ignition and biasing the grids negative. The current rapidly falls to zero; normal excitation is then reestablished automatically, and the unit resumes normal operation within about one-quarter second from the occurrence of the fault.

Protection for the rectifier transformers and backup protection for the tubes is provided by overcurrent relays, which are connected to current transformers in the a-c circuits and trip the oil circuit breakers.[21]

Installation and Operation

The rectifier transformers and oil circuit breakers are installed outdoors. The rectifier tubes with their auxiliaries and control equipment are housed in a windowless, air-conditioned building, the first floor of which is located above the main transformers. This arrangement was used because the location is in a flood area, and because available ground space was limited. A view of the installation is shown in Figure 38. The rectifier tubes are enclosed in cubicles on the second floor of the building. The control panels and the anode disconnects are installed on the lower floor. Each 10,000-kw unit has a recirculating cooling system, with a water-to-water heat exchanger, for cooling the ignitron tubes.[25]

The over-all efficiency of the Edgar Thompson frequency changer exceeds 90 to 93 per cent under most operating conditions. The power factor of the power rectifiers ranges between 85 and 95 per cent, and for the power inverters is between 75 and 85 per cent, depending upon the load and a-c system conditions.

The frequency changer operates usually in the 60-cycle to 25-cycle direction, but there have been instances when operation in the other direction was necessary. During some periods of power shortage on the 25-cycle system in the past year the converter was required to deliver power continuously at considerably above its full-load rating, and it performed successfully.

Life of the pentode ignitrons has exceeded expectations, and a majority of the original tubes are still in service. Most of the problems in this installation have been those of making correct adjustments of the automatic phase-control and temperature-regulating equipments. Before achieving the final correct adjustments, the frequency of faults was greater than desired by the designing engineers, but not excessive from an operating standpoint. A goal of not more than ten faults per day (24 hours) was set by the designers. This was eventually bettered, and under these conditions operation can be considered highly successful.

Frequency Changer for Induction Heating

Another type of electronic frequency changer, employing mercury-arc rectifiers, has been applied for converting a-c power from a polyphase system of a commercial frequency, such as 60 cycles, to single-phase power at a frequency of about 1,000 cycles, for induction heating and melting of metals.[26] The diagram of the power circuit is shown in Figure 39.

Power Circuit and Control

The frequency changer consists of a polyphase low-frequency rectifier trans-

former with a 3-phase zig-zag d-c winding, a single-phase high-frequency inverter transformer, and a 6-anode rectifier. The circuit consists of an induction heating coil with a parallel bank of capacitors *C*. The rectifier cathodes are connected to the neutral point of the rectifier transformer d-c winding through a d-c reactor. The transformer windings are represented by their voltage vectors. Each phase of the rectifier transformer is connected to a d-c winding section of the inverter transformer and a pair of rectifying elements. The rectifier transformer is connected to the a-c supply circuit through a circuit breaker.

The rectifier serves both as a power rectifier and a power inverter. The three pairs of rectifying elements operate as a 3-phase power rectifier, and each pair carries the direct current during approximately one-third of a cycle of the low-frequency voltage. During the conducting period of each pair, the two rectifying elements operate as a power inverter, and the current is switched between them every half-cycle of the high-frequency voltage. The high-frequency voltage required for commutating the current between the two rectifying elements of each pair is generated in the load circuit by oscillation between the induction coil and the capacitor. The actual operating frequency of the output voltage is determined by the constants of the load circuit. The power is supplied to the load circuit at a leading power factor, which is a requisite condition for the operation of a power inverter.

The control voltage for the grids of the rectifier is obtained from the output circuit. The output power can be regulated by phase control of the rectifier, with grid or ignition control at the low frequency (power-rectifier operation). A limited range of power regulation can be effected also by phase control at the high frequency (power-inverter operation).

The frequency changer is started by closing the a-c circuit breaker and applying a starting voltage to the control grids of the rectifier. A resistor is connected in the d-c circuit on starting and is short-circuited automatically when a high-frequency voltage is produced at the load terminals. While in service, the frequency changer can be stopped and started by push-button control without operating the a-c circuit breaker.

Some variations of the circuit in Figure 39 are possible, to permit using a high-frequency transformer with a single d-c winding. When sealed-tube rectifying elements are employed, they can be arranged in groups of three, with the high-frequency d-c winding connected between the cathodes of the two groups, and with the midpoint of this winding connected to the d-c reactor. The tubes of each group are connected to the three phases of the 60-cycle d-c winding. Another alternative connection is to divide the low-frequency d-c winding into two identical zig-zag sections, which are closely interlaced, and connect the high-frequency d-c winding between their neutrals.

When the rating of the unit requires twelve rectifying elements, the low-frequency transformer is provided with a 6-phase d-c winding, which improves the wave shape of the a-c line current.

Application

A number of electronic frequency-changer installations of this type have been made in the United States, for outputs of 250 to 600 kw. Most of them are used for supplying power to induction melting furnaces in brass and steel foundries. This type of frequency converter involves more equipment and more elaborate control circuits than the motor-generator type frequency changer used for induction heating. However, the electronic frequency changer has some notable advantages over the rotating type.

It consists of stationary equipment. It has a higher full-load efficiency (90 to 93 per cent), the efficiency curve is fairly flat over most of the load range, and the idling losses are low. The frequency is not fixed and can adjust itself to the load circuit, so that it is not necessary to switch capacitors when the load power factor changes, which occurs during a furnace melt, for example.

The application of this type of frequency converter is limited to the lower range of frequencies used for induction heating, because of the limitation imposed by the deionization time of mercury-arc rectifying devices.

Part VII. Inductive Co-ordination

Direct-Current Circuit

The d-c output voltage of a rectifier has ripples, because it is made up of portions of sine-wave voltages (see Figure 42). The ripple frequency is equal to the product of the a-c line frequency and the number of rectifier phases. The larger the number of phases the smaller is the ripple. Phase control of the rectifier, used for regulating the output voltage, increases the magnitude of the ripple. The voltage ripple can be resolved by a Fourier series into sinusoidal harmonic components.[1,24] The first harmonic has the same frequency as the ripple. The frequencies of the higher harmonics are multiples of this frequency. For example, the d-c voltage of a 6-phase rectifier supplied from a 60-cycle a-c system has harmonic components of 360, 720, 1,080, 1,440, and so forth, cycles. In general, the higher the order of an harmonic the smaller is its magnitude.

The harmonic components of the voltage cause the flow of harmonic currents in the d-c load circuit, the magnitude of any current harmonic being equal to the ratio of the harmonic voltage to the circuit impedance at the harmonic frequency. For most applications using rectifiers with six or more phases, the effect of these currents are negligible. Sometimes a reactor is connected in series with a 6-phase rectifier supplying electrolytic cells which have a high back-electromotive force and low resistance, such as zinc-producing cells or storage batteries, in order to reduce the magnitude of the sixth-harmonic current and the additional losses caused by it in the cells.

While the harmonic components of the rectifier output voltage and current usually are too small to affect the power-utilization equipment connected to the d-c circuit, they sometimes cause disturbances in communication circuits which have inductive exposures to the d-c load circuit. This has occurred on some street railway systems with overhead trolley wires or feeders and ground return. Harmonic currents were induced into adjacent telephone circuits, through capacitive or magnetic coupling, and caused objectionable noise.

Figure 39. Power circuit of electronic frequency changer used for converting polyphase low-frequency power to single-phase high-frequency power for induction heating

Where such interference with communication circuits occurred, it was eliminated by filtering the output voltage of the rectifier, using a series reactor and resonant shunt filters as shown in Figure 40. Each branch of the shunt filter consists of a reactor L in series with a capacitor C which are in resonance at the frequency of the harmonic to be eliminated. The filter serves as a short circuit for the harmonic voltage, and the series reactor limits the harmonic currents through the filter. For 6-phase rectifiers, filter branches for the first three or four harmonics have been found adequate. One or two branches usually are sufficient for 12-phase rectifiers, when correction is needed.[8]

Alternating-Current Circuit

The a-c line current of rectifier units has a step-type wave shape,[1] which can be resolved into a sinusoidal component of line frequency and various harmonic components.[11,24] For most rectifier circuits, there are two harmonics in the a-c line current for each harmonic in the d-c output voltage. For a 6-phase rectifier, the a-c currents have the 5-th, 7-th, 11-th, 13-th, 17-th, 19-th, 23-rd, 25-th, (and so forth) harmonics. The a-c currents of a 12-phase rectifier have the 11-th, 13-th, 23-rd, 25-th, (and so forth) harmonics. The larger the number of rectifier phases the fewer harmonics are present and the higher is the order of the lowest harmonic.

The magnitudes of the harmonic currents have a definite relation to the magnitude of the total rectifier current and depend also on the order of the harmonic. In general, the higher the order of an harmonic the smaller is its magnitude. The use of phase control increases the magnitude.

Occasionally, the harmonic components of the rectifier a-c line currents cause interference in communication circuits exposed to the a-c circuits. Such interference has occurred in only a small percentage of rectifier installations. However, when the problem arises it usually is more involved than on the d-c circuit,

Figure 40. Filter for d-c output voltage of rectifier unit

Figure 41. Vector diagram of phase-shifting autotransformer used for multiphasing rectifier installations

because of the larger number of harmonics and the greater extent of a-c systems. From the point of view of the a-c system, a rectifier installation can be considered as a generator of harmonic currents, which can flow into various branches of the system depending on their impedances. They do not necessarily have to flow to the power supply source only.

The probability of interference is practically nil for urban rectifier installations supplied by cable. The probability of an induction problem is greatest when a rectifier installation is supplied from a power system which has rural distribution lines supplying single-phase loads, and long open-wire telephone lines parallel the power-distribution lines.

Where there is a probability of interference, it is advisable to use as many rectifier phases as possible for the rating of the installation. In installations with a number of parallel rectifier units supplying a load, as in electrochemical plants, the number of rectifier phases can be increased by shifting the phases of the a-c supply voltages to the individual units.[12] This has been accomplished by using phase-shifting autotransformers connected as shown in Figure 41. The voltages to the rectifier transformer can be shifted with respect to the a-c line voltages by any angle θ, in the lagging or leading direction, by connecting terminals ABC to the line and terminals $A'B'C'$ to the transformer, or vice versa. The application of this method of multiphasing is illustrated in Figures 25 and 26, where a 36-phase rectifier system was obtained with six 6-phase units by using four 10-degree phase shifters.

Interference in communication circuits is less likely to occur on rectifier installations supplied by high-voltage feeders, because the rectifier line current is lower and there are fewer close exposures between telephone lines and high-voltage power lines.

When interference occurs, it can be cor-

rected sometimes by relatively inexpensive changes in the power or telephone systems. When such remedies are not possible or are too costly, the interference can be eliminated by using a filter on the line side of the rectifier transformer. Such a filter usually consists of reactors in series with the line and capacitors across the line, between the reactors and the rectifier transformer. The capacitors provide a low-impedance bypass for the harmonics, and the reactors impede their flow into the line. If the interference is caused largely by one or two harmonics, resonant shunts may be used instead of, or in addition to, capacitors. Such filters are usually fairly expensive.

When a rectifier installation is planned in a location where telephone interference might occur, it is advisable to make an investigation in advance, with the co-operation of the power and telephone companies and the manufacturer of the rectifier equipment. The probability of interference can be evaluated through such an investigation and remedial measures might be taken, if necessary, to avoid interference or to reduce its severity.

A comprehensive treatment of this subject is contained in reference 38 of the Bibliography. This report was prepared under the auspices of the AIEE electronic power converter committee. It includes relatively simple procedures, illustrated by an example, for evaluating the probability of interference from a-c systems supplying rectifiers.

Standards

A proposed standard for pool-cathode mercury-arc power converters was prepared by the AIEE electronic power converter committee and was published as an AIEE report in June 1946 (AIEE Number 6). It is expected to be issued in the near future as a standard by the American Standards Association.

The purpose of the standard is to establish uniform terminology for component parts and circuits of mercury-arc power converters, uniform symbols for circuit quantities, and standard methods of rating and testing. It includes sections on definitions, on standards for rating and tests, a test code, and sections on recommended practice, and on rectifier transformers. A table of rectifier circuits, with vector representation of the transformer voltages and standard terminal markings, is also included.

Conclusions

This paper has covered the present-day practices in the design and application of mercury-arc power converters in North America. In conclusion, some of the future trends that can be foreseen at present will be mentioned briefly. Such predictions are only estimates that could be upset by unforeseen developments in design or application requirements.

1. It is unlikely that pumped single-anode mercury-arc tubes, for a d-c rating greater than 1,000 amperes per tube, will be needed for some time to come. As the current per tube increases, the arc-drop voltage also increases and the efficiency decreases.

2. There is likely to be an increasing use of sealed tubes for still higher kilowatt outputs. Sealed tubes for current ratings higher than 400 amperes per tube will probably be developed.

3. There is likely to be an increasing application of mercury-arc converters for adjustable-speed motor drives. This application is still in its early stages, and has promising possibilities.

4. The use of high-voltage mercury-arc rectifiers for supplying power to radio-frequency oscillators, for induction and dielectric heating and for radio transmitters, is another promising application field.

5. Much has been written on the application of mercury-arc power converters for long-distance high-voltage d-c power transmission, particularly in European technical literature.[44] Experimental work on this application was carried on or is in progress in several European countries. An experimental installation has been operated also in the United States. Technically, such an application is possible, although considerable more development work is necessary. Its commercial possibilities on this continent will depend on economic factors and are unknown at present.

Appendix. Operation of Electronic Power Converters

The rectifying elements of an electronic power converter (Figure 44) can be considered as unidirectional switches, which connect the d-c circuit to each of the transformer phases, in cyclic sequence. The voltage of the d-c circuit, at any instant, is equal to the voltage of the transformer phase to which it is connected by one of the rectifying elements, minus the arc-drop voltage in the rectifying element, which will be disregarded in this discussion.

If the d-c circuit is connected simultaneously to two or more phases, the d-c voltage is equal to the average value of the instantaneous phase voltages, assuming the phase voltages and reactances are balanced.

Power Rectifier

In Figure 42 are shown the theoretical wave-shapes of the d-c output voltages for a 6-phase power rectifier with a simple star-connected transformer d-c winding, as shown in Figure 44. The positive half-cycles of the phase voltages are shown also.

Figure 42(*a*) represents the operating condition near no load, if the rectifier is permitted to conduct freely without delaying the anodes by grid or ignition control. Each phase is connected to the d-c circuit when its voltage is higher than that of the other phases, because an anode starts conducting when its voltage becomes positive to its cathode, and the common cathode connection is at the potential of the conducting phase. Phase 1 conducts until the intersection point *k* of its voltage with that of phase 2. Similarly, phase 2 conducts from *k* to *l*, phase 3 from *l* to *m*, and so forth. The conducting period of each phase is $2\pi/p$, in which p is the number of phases which conduct the direct current in succession. The voltage of the d-c circuit is indicated by the heavy trace in Figure 42(*a*), and has an average value E_{d0}.

In Figure 42(*b*) is shown the operating condition when the rectifier is carrying approximately full-load current. The anodes start conducting at the intersection points of the voltage waves as in Figure 42(*a*). However, because of the transformer reactance, a time interval is required for the transfer of the direct current from the outgoing phase to the incoming phase. During that interval, called the commutating angle u, both phases conduct current, and the voltage of the d-c circuit is equal to the average of the two phase voltages. The average of phase voltages 2 and 3 is represented by sine wave e_u, and the d-c voltage wave during the commutation period follows e_u. At the end of the commutation period, when the current of phase 2 has dropped to zero, the d-c voltage becomes equal to that of phase 3. The average value of the d-c output voltage, E_d, is lower than in Figure 42(*a*), because of the voltage reduction during the commutation periods. The com-

Figure 42. Theoretical wave shapes of d-c voltages of power rectifier

(*a*) No load, no phase control
(*b*) Full load, no phase control
(*c*) No load, with phase control
(*d*) Full load, with phase control

Figure 43. Phase control of rectifier d-c voltage, illustrating transition from power rectification to power inversion

Figure 44. Diagram of connections of electronic frequency changer for interconnecting two a-c power systems

mutating angle u increases, as the load current or the transformer reactance (commutating reactance) increases.[1,24]

Phase Control

In Figure 42(*c*) is represented the operating condition, near no load, when the start of anode conduction is delayed beyond the intersection point of successive phase voltages. This delay is accomplished by grid or ignition control of the rectifying elements and is called phase control.

The rectifying element of phase 2 is permitted to start conduction at point k' of its voltage wave, which is displaced from the normal point k by the phase control angle of retard α. Phase 1 continues to conduct the current until phase 2 starts. Similarly, phase 2 conducts from k' to l', so that the conduction period is the same as in Figure 42(*a*). The average d-c voltage, $E_{d0}\alpha$, is lower then E_{d0}, due to the voltage reductions during the angles of retard. Phase control is used for controlling the d-c output voltage of rectifiers.

In Figure 42(*d*) is represented the condition when the rectifier is carrying the same load current as in Figure 42(*b*), while operating with phase control. The starting points of the anodes are the same as in Figure 42(*c*). After phase 3 starts at point l', phases 2 and 3 conduct simultaneously during the commutating angle, until phase 3 has commutated the current away from phase 2. During this period the d-c voltage wave follows the sine wave e_u, as in Figure 42(*b*). The commutating angle u in Figure 42(*d*) is smaller than in Figure 42(*b*), because the voltage difference between the phases during commutation is greater and the transfer of current is speeded up.

The average voltage $E_{d0}\alpha$ is lower than $E_{d0}\alpha$, because of the voltage reduction during the commutation periods. The reduction in the average voltage due to the commutating angle is the same as in Figure 42(*b*).[24]

Power Inverter

In Figure 43 are shown several stages of phase control, in which the angle of retard is varied from zero to some value over 90 degrees. The angle of retard is measured in each case from the intersection point of the positive half-cycles of the phase voltages. The rectifier is assumed to operate near no load, so that the commutation periods are not shown. When operating at higher loads, the voltage during commutation would follow the sine wave of the average voltage e_u, as in Figure 42.

In Figure 43(*a*), the rectifier is operating without phase control, as in Figure 42(*a*). In Figure 43(*b*), the phase-control angle is α_1, and the average d-c voltage is indicated by the horizontal line. In Figure 43(*c*), the angle of retard, α_3, has been increased to 90 degrees, and the average voltage is zero. It is assumed that there is sufficient inductance in the d-c circuit to maintain the flow of direct current even during the negative portions of the d-c voltage wave. If there were no inductance, the current could flow only during the positive periods and would be discontinuous. The average voltage then would remain positive up to a phase-control angle of 120 degrees.

In Figure 43(*d*), the phase-control angle, α_3, is greater than 90 degrees, and phase control is extended into the negative half-cycles of the phase voltages. The d-c voltage is negative; however, the current continues to flow in the same direction through the rectifier circuit. This is made possible by applying another voltage to the circuit to overcome the negative rectifier voltage.

The change in the direction of the d-c voltage, from positive values in Figures 43(*a*) and (*b*) to a negative value in Figure 43(*d*), while the direction of current remains unchanged, necessarily involves a reversal in the direction of power flow. In Figures 43(*a*) and (*b*), power from the a-c circuit is converted to power into the d-c circuit. In Figure 43(*d*), power from the d-c circuit is converted to power into the a-c circuit, and the rectifier unit operates as a power inverter. It should be noted that the change in the direction of power flow was effected by phase control, without any change in the circuit of the rectifier unit.

Frequency Changer

The operation of a power rectifier and a power inverter is illustrated in Figure 44. The directions of the voltages, current, and power flow are indicated by arrows. The power rectifier converts power from the a-c circuit A to direct current, and the output voltage E'_d is in the same direction as the direct current I_d. In the power inverter, the voltage E_d is opposite to the direction of current I_d, and it can be considered as a back-electromotive force. The power rectifier is connected to the power inverter so that the current flows in the same direction in both circuits, from anodes to cathodes. The voltage of the power rectifier overcomes the back-electromotive force of the power inverter to cause the flow of current. The d-c power output of the power rectifier is thus converted to a-c power into the a-c system B.

In the circuit of Figure 44, power is transmitted between two a-c systems which may operate at different a-c voltages and frequencies. Such a combination is called an electronic frequency changer. This circuit is also the basis of a d-c power transmission system, with one of the rectifier units located at the sending end and the other at the receiving end of the transmission line. The transmission voltage can be increased to any desired value by connecting in series a number of rectifier units or rectifying elements at each end.

The transmitted power can be regulated by regulating the output voltage of the power rectifier or the back-electromotive force of the power inverter by means of phase control. The direction of power flow can be reversed by changing the phase position of the conducting periods in the a-c voltage cycles of the two units. This can be accomplished by means of the grid or ignition control circuits of the rectifiers, without any change in the power-circuit connections.

Power-Inversion Limit

Referring to Figure 43(*d*), the operation of a power inverter is based on the ability to delay the conduction of the rectifying elements until the negative half-cycles of their phase voltages, and on the ability to commutate (transfer) the direct current between successive phases. Current can be commutated only from a phase of lower voltage to a phase of higher voltage. In Figure 43(*d*), this condition prevails between the intersection point K of the positive half-cycles and the intersection point L of the negative half-cycles, as indicated by the shaded area.

Commutation in a power inverter must therefore be completed before point L is reached. For example, if phase 2 does not

commutate the current away from phase 1 before point L, phase 1 will continue conducting beyond point L (when its voltage becomes higher than that of phase 2) and into its positive half-cycle. The inverter back-electromotive force will then disappear, and an inverter fault, called an arc-through, will result. Such a fault imposes a short circuit on the d-c power supply, through the faulted rectifying element and its transformer phase, and a high fault current can result. To avoid such a fault, the conduction of phase 2 must be started at a point on its voltage wave, which precedes point L by a sufficiently large angle of advance β, so that the commutating angle u' at the highest operating current is less than β. The cathodes of the rectifying elements are at the potential of the heavy trace in Figure 43(d). Between the end of commutation and point L, the anode of the rectifying element connected to phase 1 (which stopped conducting) is negative to the cathode. This negative period is needed for dionization of the rectifying element, so that its grid will regain control and keep the anode from firing when it becomes positive to the cathode after point L. This negative period is called the margin angle γ and is equal to $\beta - u'$. The minimum margin angle depends on the design of the rectifying elements.

Radio for Telephone Service in America

H. I. ROMNES
MEMBER AIEE

IT IS a curious fact that the term "radiophone" was applied to the wireless transmission of speech many years before Marconi first demonstrated wireless. This came about when in 1880 Alexander Graham Bell sent speech over a light beam and Mercardier of France, in describing the experiment, called it the "radiophone." However, radio, as we now know it, got its start as a practical means of communication with the demonstration by Marconi. For the first 25 years, radio was used almost exclusively for telegraph but the possibility of using it for the transmission of speech was recognized very soon and within ten years speech transmission had been accomplished in the laboratory by several experimenters, both in America and Europe. However, the practical application of radiotelephony had to await the discovery of means for generating stable radio frequencies, for modulating them with speech and for amplifying the radio frequency energy.

The tool for doing all these things turned out to be the 3-element vacuum tube which was invented by de Forest in 1906 and developed into a successful amplifier, oscillator, and modulator during the 1912–1915 period. The door was then open to radiotelephony and results came quickly. Early in 1915, a vacuum tube transmitter of a few watts' power gave speech transmission over a distance of about 600 miles, using frequencies that ranged from 170 to 375 kc (1,800 to 800 meters). Later that same year, a transmitter employing hundreds of vacuum tubes in parallel to produce an output power of 2 or 3 kw was used to transmit speech from Arlington, Va., to the Canal Zone, the Pacific Coast, Hawaii, and Paris. In 1916, tests of 2-way radiotelephony were conducted with ships of the United States Navy. In 1917–18, fairly large quantities of radiotelephone equipment were produced for communicating with ships and airplanes and for other war purposes but radiotelephony became available too late to be of great use in World War I.

The first use of radio for regular public telephone service occurred in 1920 when a 2-way radiotelephone system was set up on the Pacific Coast between Catalina Island and Long Beach, Calif., a distance of 32 miles. This radio circuit was extended over wire lines to Los Angeles, Calif., and the rest of the Bell System. The system was used successfully for about three years. By that time, the growth in the telephone traffic to the island made necessary additional circuits in sufficient number to justify a submarine cable. Furthermore, the frequency band in which the radio system operated had been assigned to the rapidly growing broadcasting service.

The first practical demonstrations of high seas ship–shore radiotelephony also were made in 1920, but because the frequencies employed were needed for broadcasting and because of the postwar slump in shipping, these experiments were not carried to the point of providing commercial service.

Overseas Radiotelephony

After 1915 distance was no longer a limitation to talking by telephone over wire lines anywhere within the United States. The oceans, however, still remained a barrier to further expansion of the range of the telephone. Since radio offered hope of overcoming this last barrier to world-wide telephony, it was natural that early emphasis should be given to overseas radiotelephony.

The early experience with radiotelephony had demonstrated that the establishment of a reliable transatlantic radiotelephone circuit would require considerably more power than was practicable in the early 1920's. The development of higher power vacuum tubes was therefore undertaken and by about 1925 water-cooled vacuum tubes had been developed which permitted generation of many kilowatts of high power at radio frequencies. Also, the single sideband, suppressed carrier method of operation had been developed so that the available power could be used efficiently for telephony. Furthermore, means for interconnecting wire and radio circuits had been developed. Tests were then started with the British Post Office which resulted in a 2-way telephone circuit across the Atlantic Ocean being opened to the public on January 7, 1927. This circuit operated at 60 kc (5,000 meters) and is still available for use when transmission conditions at other frequencies are unsatisfactory.

The number of long-wave channels available is so limited that very little overseas service could be handled in this range. Furthermore, the long-wave system requires immense antenna structures and very high power, with the result that costs are so great as to discourage its use. However, it was soon discovered that short waves in the range of 3,000 to 30,000 kc could be transmitted over great distances. This opened up frequency space for an extensive increase in the number of radio channels. Furthermore, the use of short waves permitted moderate sized antennas which could be arranged to provide some measure of directivity and so reduce the amount of power required. These features made radio more economically attractive, permitting reductions in rates and resulting in rapid expansion of service.

The first short-wave radiotelephone circuit to London was opened for public service on June 1, 1928. In view of its success, circuits were soon established to

Paper 48-189, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted October 16, 1947; made available for printing June 11, 1948.

H. I. ROMNES is radio engineer with the American Telephone and Telegraph Company, New York, N. Y.

Figure 1. Overseas radiotelephone service from the United States

Figure 2. Growth in overseas radiotelephone traffic

other points in Europe and to South America, Central America, and over the Pacific Ocean. The present extent of the overseas radiotelephone network radiating from the United States is shown in Figure 1, and the growth in the number of messages and the reduction in rates is shown in Figures 2 and 3. There are now four overseas operating points in the United States. Through them, any one in this country can now talk to any country in the world having substantial telephone development, except for a few areas where communications are not back to normal since the war's end.

One end of a modern transatlantic radiotelephone circuit is shown diagrammatically in Figure 4. The connection from the subscriber, who may be located anywhere within the entire telephone system, appears at the overseas switchboard as a 2-wire telephone circuit. From there it passes to the transmitting branch of the radio circuit through a hybrid coil which prevents most of the incoming radio speech from going back out on the transmitting branch. Proceeding along the transmitting branch, the outgoing speech is regulated by a *vogad* (voice operated gain adjusting device) which brings it to practically constant volume of such value as to efficiently modulate the radio transmitter. The speech then actuates a *vodas* (voice operated device antisinging) which closes through the speech path to the transmitter and simultaneously blocks the receiving path during each actual speech spurt. This is necessary in order to prevent singing due to signals circulating around the radio circuit through the distant terminal when large gains are introduced to offset low volume. At this point in the circuit is shown one form of privacy device which is brought in to make the speech unintelligible to the casual listener. This is done by splitting the speech band into several smaller frequency bands which are then interchanged and some of them inverted to produce an unintelligible "scrambled" mixture. The "scrambling" combinations are changed rapidly in synchronism with similar changes at the distant terminal, in accordance with a prearranged schedule. The privacy device is transferred between the transmitting and receiving branches of the circuit by the *vodas* relays as required.

The "scrambled" speech from the privacy equipment passes either directly or through a channel shifter over a wire circuit to the radio transmitting station, which may be 40 miles or more away. The channel shifter is used in a multichannel radio system to displace channels from their normal frequency position with reference to the radio carrier so as to permit two or three channels to be transmitted simultaneously through a single transmitter.

The modern overseas radiotelephone transmitter is of the single sideband type in which only one sideband is used to transmit any particular speech band. In 2-channel single sideband systems, a different speech channel is carried by each sideband. Several of these systems at present are carrying three speech channels each and in these the third channel is divided between the two sidebands. In all cases, the carrier is transmitted at greatly reduced power, just sufficient to permit its being received at the distant terminal in enough strength to be used as a reference in the automatic volume control and automatic frequency control circuits.

The reduction of transmitted carrier, together with the fact that only a single sideband is used for any one channel, results in a net improvement in signal to noise ratio at the receiver of approximately nine decibels as compared with a double sideband circuit.

Figure 3. Overseas telephone service—reductions in rates

Rhombic antennas are used for the most part for both transmitting and receiving. These are of simple construction, have good directivity and operate efficiently over the entire frequency range used in any overseas service.

The received speech from the distant radio terminal is amplified and demodulated in a single sideband radiotelephone receiver. This receiver has arrangements for either simplifying the reduced carrier which was transmitted and then using this for demodulation purposes, or for using a local oscillator for this purpose. It also includes an arrangement for automatically tuning the receiver so that it follows accurately any slight variations which may occur in the carrier frequency of the distant transmitter. The receiver separates out the voice frequencies demodulated from the two sidebands, passes them through receiving *vogads* to produce

Figure 4. One end of typical transatlantic radiotelephone circuit

Figure 5. Land stations for serving high-seas, coastal, and harbor vessels

constant volume and then sends them over wire circuits to the control terminal, sometimes more than 100 miles away.

In the control terminal, the received speech passes through a channel restorer if required, then goes in succession through the privacy device for unscrambling, the *vodas*, a noise reducer which operates the suppress noise during pauses in received speech, and finally through the hybrid coil where it is recombined with the outgoing path to form the 2-wire circuit again at the overseas switchboard.

Mobile Radiotelephony

Radio is the only method available for communicating with mobile units at a distance, so that from the very beginning this use of radio has been emphasized. While radiotelegraph has been predominant in this field for most of the period since the inception of radio, in the last decade mobile radiotelephony has made vast strides as the opening up of new frequency ranges has made it possible to extend the service to more users.

Radiotelephone Service to Ships

Tests of radiotelephone service to high seas ships were made as early as 1916 with the United States Navy and in 1920 with commercial vessels. However, it was not until 1929, when the Leviathan was equipped, that telephone service to the public on ocean going vessels was established. For this service the shore station equipment is generally similar to that employed for short-wave overseas service. By the time World War II interrupted high seas service to the public, it had been made available on 39 of the largest liners on both the Atlantic and Pacific Oceans. The service has now been resumed on the Queen Mary, Queen Elizabeth, the S.S. America, and a few other of the larger ships, with the number of calls handled from each ship several times greater than was experienced before the war, sometimes running as high as 75 calls in a day from a single vessel.

The radio equipment for high seas service needs to be of a relatively high power and arranged for operation on several frequencies in order to give reliable service at various distances and at various times of the day. For vessels which operate within harbors or along the coasts, an arrangement can be used which is simpler and more economical both to install and to operate. Therefore, the high seas service from the United States has been supplemented by a comprehensive system of 15 coastal harbor stations placed at strategic intervals along the Atlantic, Gulf of Mexico, and Pacific coasts, as shown in Figure 5. These stations operate on frequencies in the two-to-three megacycle range, different frequencies being used for transmitting and receiving and a separate pair of frequencies being assigned for the different stations within a fairly large area.

A typical land station for the coastal and harbor service consists of a radio transmitter, usually of about 400 watts power, and several radio receivers remotely controlled from the switching center over wire lines. By providing receivers at several favorable locations along the coast, the transmitting ranges of the low powered ship sets and the higher powered shore transmitter are brought into balance. Typical transmitting and receiving stations are pictured in Figures 6 and 7. These are connected to the switchboard through an automatic control terminal which switches the system back and forth from transmit to receive as the conversation shifts from one party to the other. The control terminals also provide an automatic gain adjusting device to apply a constant volume to the radio transmitter and include arrangements for signaling ships and for receiving signals from ships.

A typical ship station consists of a radio transmitter and radio receiver connected to a hand telephone set having a push-to-talk key which causes the carrier to be transmitted when the key is depressed and the receiver to be connected when the key is released. Several sizes of sets are available, ranging in power from about 10 watts to 100 watts. Figure 8 pictures such an installation aboard a tugboat.

In making a call from a ship, the user simply picks up the hand set and pushes the key momentarily. This sends out a spurt of carrier which is picked up by one or more shore receivers to operate relays which light one or more lamps at the switchboard. The operator plugs into a jack associated with one of the lighted lamps. This operation automatically

Figure 6 (left). Coastal-harbor radiotelephone transmitting station

Figure 7 (right). Coastal-harbor radiotelephone receiving station

Figure 8. Radiotelephone installation aboard tugboat

selects the associated receiver, starts the shore transmitter, and places the system in the transmitting condition. The operator answers the call by saying, for example, "This is the Norfolk, Marine Operator." The ship user then depresses his push-to-talk key, which sends out carrier to operate a relay in the shore control terminal to switch the system to the receiving condition, and gives his instructions to the operator who completes the connection over the regular telephone system in the normal manner.

To make a call from a shore telephone to a ship, the shore subscriber reaches the marine operator over the regular wire telephone network, giving her the information as to the ship being called. The operator plugs into the jack associated with the system and, if the called ship is equipped for selective signaling, dials the code for the ship being called. This sends out alternate pulses of 600 and 1,500 cycle tones which operate selectors on all ships within range which are equipped for selective signaling, but only the selector whose code is dialed will close a contact to ring a bell. For ships not equipped with selective signaling the operator calls by sending an attention tone and then announcing the name of the ship being called.

The coastal harbor service has proved to be very popular, there being more than 5,000 ships registered for the service at the end of 1946. During 1946, more than 200,000 calls were handled through the coastal harbor stations. These stations also are being used to a limited extent for service to airplanes.

In addition to the 15 stations along the seacoast, there are a number of similar stations around the Great Lakes and along the largest rivers. These, also, are shown in Figure 5.

General Mobile Service

As long as radio was limited to the lower frequencies, the number of channels available for mobile service was so small that they were reserved largely for use where safety of life was involved, for example, to ships at sea. During the 1930's, the usable frequency range was gradually pushed upward beyond 100 megacycles. Not only did this increase the number of frequency bands available but because of the lack of skywave transmission at the higher frequencies, the assignments could be reused at fairly short geographical spacings. In the 1930's therefore, it became practical to extend mobile radio to police and fire departments, to public utilities and to other emergency applications.

World War II accelerated the development of mobile radiotelephone equipment and the further extension of the usable frequency range. It now became possible to assign a little frequency space for other than emergency services. When the war ended, a few frequencies were made available for a trial of general mobile service of two types:

Figure 10. Radiotelephone transmitter and receiver installation in automobile

1. Urban service operating in the 152–162 megacycle range and intended to cover a limited area, usually a city and its surrounding suburbs.

2. Highway service operating in the 30–44 megacycle range and intended primarily to serve vehicles or other mobile units traveling on highways or waterways between cities.

For highway service, stations are placed at intervals of about 50 to 100 miles, depending upon terrain, so as to give continuous coverage along the more important highways. The distinguishing feature of "general" mobile service is that it permits connection to be made from a mobile unit to any telephone in the worldwide network. This requires considerably different arrangements than are used for private radio systems where connections with mobile units are established from only one or a limited number of fixed points.

In the three years since the end of the war, general mobile service has been established in more than 50 cities in the United States and more than 100 systems are under construction or being actively planned. Several of these cities now have two or three stations in service. Each of these stations serves 50 to 100 mobile units, depending upon the types of calls involved. The location of the stations now in service or under construction are shown in Figure 9.

A typical station for mobile service includes a 250-watt frequency-modulated radio transmitter with its antenna on a high building or other elevation so as to provide good transmission over the area to be served. Several fixed receivers are placed at favorable locations within this area to pick up the relatively weak signals from the lower powered mobile transmitters. The transmitter and the several receivers are connected to a switchboard through a control terminal which provides the means for bringing together the two 1-way radio paths, for automatically

Figure 9. General mobile telephone service land stations

adjusting the volume to a constant value for application to the radio transmitter, for operating a switchboard signal lamp on incoming calls, for signaling particular cars on outgoing calls and for automatically checking that the transmitter is operating properly and within the required frequency tolerance. Also, arrangements may be included for automatically selecting the one receiver which is producing the best signal-to-noise ratio and cutting off the others so as not to introduce unnecessary noise. At the switchboard, connection can be made to the regular telephone network as is the case with any subscriber's line.

A typical mobile installation consists of a frequency modulated transmitter of 20- to 40-watts power and a receiver, both placed in the luggage compartment of the automobile, as shown in Figure 10; an antenna about 18-inches long mounted in the middle of the metal roof of the automobile (Figure 11); and a hand telephone set, together with the signal bell and lamp, located below the instrument panel convenient to the automobile driver (Figure 12). To place a call the mobile subscriber simply picks up the hand set and operates momentarily the push-to-talk key in the handle of the set. This causes carrier to be transmitted which is picked up by one or more of the fixed receivers, causing the switchboard lamp to light. The operator answers the call and makes the connection requested by the mobile subscriber. The mobile user presses the button when he talks and releases it when he listens, but the user at the fixed end of the connection uses his telephone just as he does for an ordinary wire connection.

Figure 11. Automobile antenna for urban mobile radiotelephone service
